

# A lottery model of density-dependent selection in evolutionary genetics

*Keywords:* r/K selection, absolute fitness, eco-evo, Grime's triangle, competition-colonization trade-off, fluctuating selection, storage effect.

## Abstract

Fitness is typically represented in heavily simplified terms in evolutionary genetics, often using constant selection coefficients, to make it easier to infer or predict how type frequencies change over time. This excludes fundamental ecological factors such as dynamic population size or density-dependence from the most genetically-realistic treatments of evolution, a problem that inspired MacArthur's influential but problematic  $r/K$  theory. Following the spirit of  $r/K$ -selection as a general-purpose theory of density-dependent selection, we develop a new model of density-dependent selection by generalizing the fixed-density classic lottery model of territorial acquisition to accommodate arbitrary population densities. We show that, with density dependence, co-existence is possible in the lottery model in a stable environment. Inspired by natural *Drosophila* populations, we consider co-existence under strong, seasonally-fluctuating selection coupled to large cycles in population density, and show that co-existence (stable polymorphism) is promoted via a combination of the classic storage effect and density-regulated population growth. We also show that the only significant bias introduced by selection at the different environmental extremes of Grime's triangle is the relative importance of competitive ability at different densities, confirming an important role for phenotypic constraints in shaping "primary strategies".

18 “...the concept of fitness is probably too complex to allow of a useful mathematical devel-  
19 opment. Since it enters fundamentally into many population genetics considerations, it is re-  
20 markable how little attention has been paid to it.” — Warren J. Ewens, *Mathematical Population*  
21 *Genetics I*, 2004, pp. 276

## 22 **Introduction**

23 Evolutionary models differ greatly in their treatment of fitness. In models of genetic evolution,  
24 genotypes are typically assigned constant (or occasionally frequency-dependent) selection coef-  
25 ficients describing the change in their relative frequencies over time. This simplified treatment  
26 of selection facilitates explicit time-dependent treatment of genotype frequencies, and can be jus-  
27 tified over sufficiently short time intervals [Ewens, 2004, p. 276]. The emphasis of population  
28 genetics is to infer past selection, migration and demographic change given a sample of nu-  
29 cleotide sequences, or to predict how allele frequencies change over time based on their relative  
30 fitness effects together with population structure, genetic drift and linkage. The resulting pic-  
31 ture of evolution excludes basic elements of the ecological underpinnings of selection, including  
32 density dependence, and how selection affects population size. This complicates the inference  
33 of past selection, because demographic changes can look genealogically very similar to selective  
34 frequency changes [Barton, 1998].

35 By contrast, models of phenotypic trait evolution use absolute fitness functions to describe  
36 how some traits of interest affect survival and reproduction in particular ecological scenarios  
37 [Diekmann et al., 2004, Metz et al., 1992]. These fitness functions can be quite problem-specific  
38 and often only account for a few traits at a time. The emphasis here is on the conditions for  
39 invasion from low frequencies and co-existence, rather than frequency or abundance trajectories  
40 over time. For instance, adaptive dynamics uses “invasion fitness” to explore the consequences  
41 of eco-evolutionary feedbacks [Diekmann et al., 2004].

42 It is challenging to generalize beyond particular traits or ecological scenarios to model fun-

damentally different forms of selection. Perhaps this is not surprising given that fitness is such a complex quantity, dependent on all of a phenotype's functional traits [Violle et al., 2007] and its environment. A detailed, trait-based, predictive model of fitness would be enormously complicated and situation-specific. It is therefore easy to doubt the feasibility of a simplified, general mathematical treatment of fitness [Ewens, 2004, p. 276]. For example, MacArthur's famous  $r/K$  scheme [MacArthur, 1962, MacArthur and Wilson, 1967] is now almost exclusively known as a framework for understanding life-history traits, and judged on its failure in that role [Boyce, 1984, Pianka, 1970, Reznick et al., 2002, Stearns, 1977]. However, the  $r/K$  scheme's original purpose was to extend the existing population-genetic treatment of selection to account for population density [MacArthur, 1962]. Few attempts have been made to develop it further along these lines.

Here we explore the interplay between some "key factors" of fitness in a simplified, territorial model of growth, dispersal and competition. This broadly follows the original spirit of MacArthur's  $r/K$  scheme. More specifically, our aim is to begin merging some ecological realism into population genetics' time-dependent, genetically-focused view of evolution. We revisit the classic lottery model of Chesson and Warner [1981], which has two features that make it well suited for this role, but one critical flaw that we rectify here.

The first feature is that the lottery representation of competition is particularly concise. Mature individuals ("adults") each require their own territory, whereas newborn individuals ("propagules") disperse to, and subsequently compete for, territories made available by the death of adults. Territorial contest among propagules leaves a single victorious adult per territory, the victor chosen at random from the propagules present, with probabilities weighted by a coefficient for each type representing competitive ability, akin to a lottery [Sale, 1977]. By comparison, coefficients for the pairwise effects of types on each other (e.g. the  $\alpha$  coefficients in the generalized Lotka-Volterra equations and the associated concept of " $\alpha$ -selection"; Case and Gilpin 1974, Gill 1974, Joshi et al. 2001), or explicit resource consumption [Tilman, 1982], are much more complicated. The second feature is the close connection between the lottery model and one of the foundational models of population genetics, the Wright-Fisher model of genetic drift, which

we discuss further below.

The critical flaw of the classic lottery model is that it breaks down at low densities (few propagules dispersing to each territory), precluding density-dependent behaviour. Our first task is to analytically extend the classic lottery model to correctly account for low density behavior (sections “Model” and “Mean field approximation”).

Using our extended lottery model evaluate the extent to which selection favors fecundity, competitive ability or lower mortality under Grime’s environments (section “Primary strategies and Grime’s triangle”). This represents a simple “sanity check” on the invasion behavior of our extended lottery model under different extremes.

We then explore some time-dependent behavior of our extended lottery model. Taking an example inspired by recent studies of rapid, seasonal evolution in *Drosophila* [Bergland et al., 2014], we discuss how environmental fluctuations might stabilize polymorphisms when population density is cyclical.

## Model

We assume that reproductively mature individuals (“adults”) each require their own territory to survive and reproduce (Fig. 2). All territories are identical, and the total number of territories is  $T$ . Time  $t$  advances in discrete iterations, each representing the time from birth to reproductive maturity. In iteration  $t$ , the number of adults of the  $i$ ’th genotype is  $n_i(t)$ , the total number of adults is  $N(t) = \sum_i n_i(t)$ , and the number of unoccupied territories is  $U(t) = T - N(t)$ .

We assume that the  $n_i$  and  $T$  are large enough that stochastic fluctuations in the  $n_i$  (“drift”) can be ignored. We derive deterministic equations for the expected change in the  $n_i$  over time, leaving the evaluation of drift for future work. This is an excellent approximation when the  $n_i$  are all large. However, we also do not evaluate the initial stochastic behaviour of adaptive mutant lineages while they are at low abundance. When considering new mutations, we therefore restrict our attention to begin with the earliest (lowest  $n_i$ ) deterministic behavior of mutant lineages (the

transition to deterministic growth occurs at an abundance  $n_i$  of order equal to their inverse expected absolute growth rate; Uecker and Hermisson 2011).

Each iteration, adults produce new offspring (“propagules”),  $m_i$  of which disperse to unoccupied territories. We assume that adults cannot be ousted from their territories, so that  $m_i$  only includes propagules landing on unoccupied territories. Propagules disperse at random over the unoccupied territories, regardless of distance from their parents, and independently of each other. There is no interaction between propagules (e.g. avoidance of territories crowded with propagules). Loss of propagules during dispersal is subsumed into  $m_i$ .

In general,  $m_i$  will increase with  $n_i$ , and will depend on population density  $N$ . For example, if  $b_i$  is the number of successfully dispersing propagules produced per genotype  $i$  adult, then the loss of propagules due to dispersal to occupied territories implies  $m_i = b_i(1 - N/T)n_i$ , akin to Levins’ competition-colonization model [Levins and Culver, 1971, Tilman, 1994]. In section “Cyclical birth and death rates” we evaluate Eq. (4) numerically using this functional form for  $m_i$ , with  $b_i$  assumed to be constant.

In the sections “Invasion of rare genotypes and coexistence” and “Primary strategies and Grime’s triangle”, we assume the simpler form  $m_i = b_i n_i$ , with constant  $b_i$ , meaning that all propagules land on unoccupied territories (a form of directed dispersal). This simplifies the mathematics without affecting the results of those sections, which only depend on the low-frequency invasion behavior of Eq. (4). Note that due to our assumption of uniform dispersal, the parameter  $b_i$  can be thought of as a measure of “colonization ability”, which combines fecundity and dispersal ability [Bolker and Pacala, 1999, Levins and Culver, 1971, Tilman, 1994].

The number of individuals of the  $i$ ’th genotype landing in any particular territory is denoted  $x_i$ . We assume that  $x_i$  follows a Poisson distribution  $p_i(x_i) = l_i^{x_i} e^{-l_i} / x_i!$ , where  $l_i = m_i / U$  is the mean territorial propagule density. This approximation becomes exact when the  $n_i$  are large enough that drift in  $n_i$  can be ignored (Appendix A).

When multiple propagules land on the same territory, the victor is determined by lottery competition: genotype  $i$  wins a territory with probability  $c_i x_i / \sum_j c_j x_j$ , where  $c_i$  is a constant

Figure 1: Each iteration of our lottery model has three main elements. First, propagules are produced by adults and are dispersed at random over the unoccupied territories (only propagules landing on unoccupied territories are shown). Lottery competition then occurs in each unoccupied territory (competition in only one territory is illustrated): each genotype has a probability proportional to  $b_i n_i c_i$  of securing the territory. Then occupied territories are freed up by adult mortality. In Eq. (3) and most of the paper, only adults can die (red crosses), but we will also consider the case where juveniles die (blue cross; section “Primary strategies and Grime’s triangle”).

representing relative competitive ability (Fig. 2).

In the classic lottery model [Chesson and Warner, 1981], unoccupied territories are assumed to be saturated with propagules from every genotype  $l_i \gg 1$ . From the law of large numbers, the composition of propagules in each territory will then not deviate appreciably from the mean composition  $l_1, l_2, \dots, l_G$  ( $G$  is the number of genotypes present), and so the probability that genotype  $i$  wins any particular unoccupied territory is approximately  $c_i l_i / \sum_j c_j l_j$ . Let  $\Delta_+ n_i$  denote the number of territories won by genotype  $i$ . Then  $\Delta_+ n_1, \Delta_+ n_2, \dots, \Delta_+ n_G$  follow a multinomial distribution with  $U$  trials and success probabilities  $\frac{c_1 l_1}{\sum_j c_j l_j}, \frac{c_2 l_2}{\sum_j c_j l_j}, \dots, \frac{c_G l_G}{\sum_j c_j l_j}$ , respectively. Genotype  $i$  is expected to win  $c_i l_i / \sum_j c_j l_j$  of the  $U$  available territories, and deviations from this expected outcome are small (since  $T$  is large by assumption), giving

$$\Delta_+ n_i(t) = \frac{c_i l_i}{\sum_j c_j l_j} U(t) = b_i n_i \frac{1}{L} \frac{c_i}{\bar{c}}, \quad (1)$$

where  $\bar{c} = \sum_j c_j m_j / M$  is the mean propagule competitive ability for a randomly selected propagule,  $L = M/U$  is the total propagule density and  $M = \sum_j m_j$  is the total number of propagules.

There is a close connection between the classic lottery model and the Wright-Fisher model of genetic drift [Svardal et al., 2015]. In the Wright-Fisher model, genotype abundances are sampled each generation from a multinomial distribution with success probabilities  $w_i n_i / \sum_j w_j n_j$ , where  $w$  is relative fitness and the  $n_i$  are genotype abundances in the preceding generation. Population size  $N$  remains constant. This is mathematically equivalent to the classic lottery model with non-overlapping generations ( $d_i = 1$  for all  $i$ ) and  $w_i = b_i c_i$ . Thus, the classic lottery model allows us to replace the abstract Wright-Fisher relative fitnesses  $w_i$  with more ecologically-grounded fecundity, competitive ability and mortality parameters  $b_i$ ,  $c_i$  and  $d_i$ , respectively. Since birth and death rates affect absolute abundances, this allows us to evaluate selection at different densities (after appropriate extensions are made), in an otherwise very similar model to the canonical Wright-Fisher. We therefore expect that drift in realized values of  $n_i$  in our extended lottery model should be similar to that in the Wright-Fisher model, but we leave this for future work.

In our extension of the classic lottery model, we do not restrict ourselves to high propagule densities. Eq. (1) is nonsensical if even a single type has low propagule density ( $l_i \ll 1$ ): genotype  $i$  can win at most  $m_i$  territories, yet Eq. (1) demands  $c_i l_i / \sum_j c_j l_j$  of the  $U$  unoccupied territories, for any value of  $U$ . Intuitively, the cause of this discrepancy is that individuals are discrete. Genotypes with few propagules depend on the outcome of contests in territories where they have at least one propagule present, not some small fraction of a propagule as would be implied by small  $l_i$  in the classic lottery model. In other words, deviations from the mean propagule composition  $l_1, l_2, \dots, l_G$  are important at low density.

We expect that a fraction  $p_1(x_1) \dots p_G(x_G)$  of the  $U$  unoccupied territories will have the propagule composition  $x_1, \dots, x_G$ . Genotype  $i$  is expected to win  $c_i x_i / \sum_j c_j x_j$  of these. Ignoring fluctuations about these two expectations (due to our no-drift, large  $T$ , large  $n_i$  approximation), genotype  $i$ 's territorial acquisition is given by

$$\Delta_+ n_i(t) = U(t) \sum_{x_1, \dots, x_G} \frac{c_i x_i}{\sum_j c_j x_j} p_1(x_1) \dots p_G(x_G), \quad (2)$$

in our extended lottery model, where the sum only includes territories with at least one propagule present. Note that unlike the classic lottery model, not all unoccupied territories are claimed each iteration, since under Poisson dispersal a fraction  $e^{-L}$  remain unoccupied.

For the majority of this manuscript we assume that mortality only occurs in adults (Fig 2; setting aside the juvenile deaths implicit in territorial contest), and at a constant, genotype-specific per-capita rate  $0 \leq d_i \leq 1$ , so that the overall change in genotype abundances is

$$\Delta n_i(t) = \Delta_+ n_i(t) - d_i n_i(t). \quad (3)$$

This seems reasonable in the absence of disturbances; when we come to consider the effects of disturbances (Section "Primary strategies and Grime's triangle"), we will incorporate disturbance-induced mortality in competing juveniles.

## Results

### Mean Field Approximation

Eq. (2) involves an expectation over the time-dependent dispersal distributions  $p_i$ , and is thus too complicated to give intuition about the dynamics of density-dependent lottery competition. We now evaluate this expectation using a “mean field” approximation.

Similarly to the high- $l_i$  approximation of classic lottery model, we replace the  $x_i$  with appropriate mean values, although we cannot simply replace  $x_i$  with  $l_i$ . For a genotype with low propagule density  $l_i \ll 1$ , we have  $x_i = 1$  in the territories where its propagules land, and so its growth comes entirely from territories which deviate appreciably from  $l_i$ . To account for this, we separate Eq. (2) into  $x_i = 1$  and  $x_i > 1$  parts. Our more general mean field approximation only requires that there are no large discrepancies in competitive ability (i.e. we do not have  $c_i/c_j \gg 1$  for any two genotypes). We obtain (details in Appendix B)

$$\Delta_+ n_i(t) \approx b_i n_i \left[ e^{-L} + (R_i + A_i) \frac{c_i}{\bar{c}} \right], \quad (4)$$

where

$$R_i = \frac{\bar{c} e^{-l_i} (1 - e^{-(L-l_i)})}{c_i + \frac{L-1+e^{-L}}{1-(1+l_i)e^{-L}} \frac{\bar{c} L - c_i l_i}{L-l_i}}, \quad (5)$$

and

$$A_i = \frac{\bar{c}(1 - e^{-l_i})}{\frac{1-e^{-l_i}}{1-(1+l_i)e^{-L}} c_i l_i + \frac{1}{L-l_i} \left( L \frac{1-e^{-L}}{1-(1+L)e^{-L}} - l_i \frac{1-e^{-l_i}}{1-(1+l_i)e^{-L}} \right) \sum_{j \neq i} c_j l_j}. \quad (6)$$

To supplement our analytical mean field derivation, we did numerical simulations of our exact density-dependent lottery model, and verified that Eq. (4) is a good approximation (Appendix B). Thus, Eq. (4) describes how type abundances change over time in a lottery model where population density can itself vary with time.

Comparing Eq. (4) to Eq. (1), the classic lottery per-propagule success rate  $c_i/\bar{c}L$  has been replaced by three separate terms. The first,  $e^{-L}$ , accounts for propagules which land alone on

187 unoccupied territories; these territories are won without contest. The second,  $R_i c_i / \bar{c}$  represents  
 188 competitive victories when the  $i$  genotype is a rare invader in a high density population: from  
 189 Eq. (5),  $R_i \rightarrow 0$  when the  $i$  genotype is abundant ( $l_i \gg 1$ ), or other genotypes are collectively  
 190 rare ( $L - l_i \ll 1$ ). The third term,  $A_i c_i / \bar{c}$ , represents competitive victories when the  $i$  genotype  
 191 is abundant:  $A_i \rightarrow 0$  if  $l_i \ll 1$ . The relative importance of these three terms varies with both  
 192 the overall propagule density  $L$  and the relative propagule frequencies  $m_i/M$ . If  $l_i \gg 1$  for all  
 193 genotypes, we recover the classic lottery model (only the  $A_i c_i / \bar{c}$  term remains, and  $A_i \rightarrow 1/L$ ).

## 194 Coexistence in constant and cyclical environments

195 In the previous section we only considered how  $b$ ,  $c$  and  $d$  should respond to selection in Grime's  
 196 environmental extremes, based on invasion fitness. Here we further explore the low frequency  
 197 behavior of Eq. (4) to determine which types can coexist in a constant environment, and then  
 198 consider the full time-dependent behaviour of Eq. (4) in a cyclical environment.

199 In a constant environment, stable coexistence is possible in our extended lottery model. A  
 200  $b$ -specialist  $i$  and  $c$ -specialist  $j$  ( $b_i > b_j$ ,  $c_j > c_i$ ) can co-exist because then propagule density  
 201  $L$  is frequency-dependent, and so is the importance of competitive ability (Appendix D). This  
 202 is a version of the classic competition-colonization trade-off [Levins and Culver, 1971, Tilman,  
 203 1994]; the competitor ( $c$ -specialist) leaves many territories unoccupied (low  $L$ ) due to its poor  
 204 colonization ability (low  $b$ ), which the colonizer ( $b$ -specialist) can then exploit. A similar situation  
 205 holds for coexistence between high- $c$  and low- $d$  specialists; a "competition-longevity" trade-off  
 206 [Tilman, 1994]. These forms of co-existence require density dependence (being mediated by  $L$ ),  
 207 and are not present in the classic lottery model. Coexistence is not possible between  $b$ - and  
 208  $d$ -specialists in a constant environment (Appendix D).

209 Now suppose that birth and death rates vary periodically with amplitude sufficient to cause  
 210 large changes in population density. This example is inspired by natural *Drosophila* populations,  
 211 which expand rapidly in the warmer months when fruit is abundant, but largely die off in the  
 212 colder months. Along with this seasonal population density cycle, hundreds of polymorphisms

exhibit frequency cycles that are in phase with the seasons [Bergland et al., 2014]. Some of these polymorphisms may be adaptive and potentially millions of years old, suggesting stable coexistence [Bergland et al., 2014, Messer et al., 2016]. Selection on allele frequencies thus occurs on the same time scale as population demography, a situation vastly more complicated than classical sweeps in demographically stable populations [Messer et al., 2016].

The classical population genetic treatment of fluctuating selection suggests that environmental fluctuations do not promote coexistence. Allele frequencies are successively multiplied by relative fitness values for each environmental iteration, and so two alleles favored in different environments can only stably coexist if the product of fitnesses for one type exactly equals the product for the other [Dempster, 1955]. Thus, stable coexistence still requires frequency-dependent selection or heterozygote advantage (as is required in a constant environment).

This classical argument overlooks two general mechanisms that promote coexistence in fluctuating environments [Messer et al., 2016]. The first is the classic version of the storage effect, which occurs when part of the population is protected from selection (due to overlapping generations in the lottery model; Chesson and Warner 1981). The second is the bounded population size effect of Yi and Dean [2013], which occurs when each environmental cycle involves growth from low to high density, with the time spent growing each cycle dependent on the fitness of the types present.

Fig. 4a-c shows the behavior of Eq. (4) for an example where  $b$  and  $d$  cycle between zero and positive values (“summers” with rapid growth and no mortality, and “winters” with mortality and no growth). Both the storage effect (adults are sheltered from selection during the summer growth phase) and the bounded density effect (expansion to high density occurs every cycle) are operating. Two types are present, a  $b$ -specialist, which is better at rapidly growing in the summer (higher  $b$ ), and a  $d$ -specialist which is better at surviving the winter (lower  $d$ ). Neither type has an advantage over a full environmental cycle, and they stably coexist. This is due to a combination of the storage and bounded density effects (recall that stable coexistence between  $b$  and  $d$  specialists was not possible in a constant environment).

The classic lottery model (Eq. 1) fails to give co-existence for these parameters because expansion to carrying capacity occurs immediately at the start of the summer (Fig. 4d-f). As a result, coexistence requires that the winter survivor's  $b$  must be about 5 times smaller than required when we properly account for the growth in the abundance of each type using Eq. (4) (keeping the other parameters the same; Fig. 4g-i). Previous models of the promotion of genetic variation via the storage effect [Ellner and Hairston Jr, 1994] similarly assume that the total number of offspring per iteration is constant, and would produce a similar error.

## Discussion

It is interesting to compare the predictions of the extended lottery model with earlier approaches, such as the  $r/K$  scheme, where  $r = b - d$  is the maximal, low-density growth rate [Pianka, 1972]. Confusingly, the term “ $K$ -selection” sometimes refers generally to selection at high density [Pianka, 1972], encompassing both selection for higher saturation density [MacArthur and Wilson, 1967] and competitive ability [Gill, 1974]. Contrary to predictions of an  $r/K$  trade-off, empirical studies have shown that maximal growth rate at low density and the high density at which saturation occurs (measured by abundance) are positively correlated, both between species/strains [Fitzsimmons et al., 2010, Hendriks et al., 2005, Kuno, 1991, Luckinbill, 1979], and as a result of experimental evolution [Luckinbill, 1978, 1979]. From the perspective of our model, this positive correlation is not surprising since the saturation density, which is determined by a balance between births and deaths, increases with  $b$ .

There is support for a negative relationship between competitive success at high density and maximal growth rate [Luckinbill, 1979], consistent with a tradeoff between  $r$  and the competitive aspect of  $K$ . This could be driven by a tradeoff between individual size and reproductive rate. To avoid confusion with other forms of “ $K$ -selection”, selection for competitive ability has been called “ $\alpha$ -selection” after the competition coefficients in the Lotka-Volterra equation [Case and Gilpin, 1974, Gill, 1974, Joshi et al., 2001]. However, competitive success as measured by  $\alpha$  (i.e. the

Figure 2: Stable coexistence between  $b$  and  $d$  specialists in a fluctuating environment requires a much greater  $b$  advantage in the classic lottery model compared to our density-dependent extension of it when population density is seasonally cyclical. (a) Birth and death rates seasonally alternate being nonzero (white for winter, green for summer). The  $b$ -specialist (black) has higher  $b$  and  $d$  ( $b = 0.5$ ,  $d = 0.2$ ) than the  $d$ -specialist ( $b = 0.217$ ,  $d = 0.1$ ) (blue). (b) Both types grow during the positive  $b$  phase, and decline during the positive  $d$  phase, but the  $d$ -specialist does so at a lower rate. Total height (blue+black) is population density  $N/T$ . (c) Summer favors the  $b$  specialist, winter the  $d$ -specialist, and they stably coexist. (d-f) Same as (a-c) for the classic lottery model; the types no longer coexist. (g-i) Same as (d-f) where now  $b = 0.0421$  for the  $d$  specialist and the types coexist. For illustration, the propagule abundances are assumed to have the form  $m_i = b_i(1 - N/T)n_i$ , reflecting non-directed dispersal.

per-capita effect of one genotype on another genotype's growth rate) is only partly determined by individual competitive ability — in the presence of age-structured competition and territoriality, it also includes the ability of each genotype to produce contestants i.e.  $b$  in our model. Our  $c$  is strictly competitive ability only — as such, changes in  $c$  do not directly affect population density (the total number of territories occupied per iteration is  $\Delta_+ N = U(1 - e^{-L})$ , which does not depend directly on the  $c_i$ ). The clean separation of a strictly-relative  $c$  parameter is particularly useful from an evolutionary genetics perspective, essentially embedding a zero-sum relative fitness trait within a non-zero-sum fitness model. This could have interesting applications for modeling the impacts of intra-specific competition on species extinction, for example due to clonal interference [Desai and Fisher, 2007, Gerrish and Lenski, 1998] between  $c$ -strategists on the one hand, and  $b$ - and  $d$ - strategists on the other.

$K$ -selection in the narrow logistic sense of selection for a greater environmental carrying capacity for given  $r$ , sometimes referred to as “efficiency” [MacArthur and Wilson, 1967], could be represented in our model by smaller individual territorial requirements. To a first approximation, two co-occurring genotypes which differ by a small amount in their territorial requirements only should have the same fitness, since the costs or benefits of a change in the amount of unoccupied territory is shared equally among genotypes via the propagule density per territory  $L$ . The situation is more complicated when the differences in territorial requirements become large enough that territorial contests can occur on different scales for different genotypes. We leave these complications for future work.

Our realization of Grime's triangle (Fig. 1) differs from approaches which identify primary strategies as trait combinations that can stably co-exist [Bolker and Pacala, 1999], referring instead to the direction and rate of ongoing adaptive trait evolution under different regimes of stress and disturbance, which is closer in spirit to Grime's arguments [Grime, 1974, 1977]. Moreover, our formulation is mathematical, in contrast to Grime's original verbal and descriptive approach, which is a recognized hindrance to the evaluation or broader application of the C/S/R scheme (e.g. Tilman 2007). However, section “Primary strategies and Grime's triangle” suggests that,

apart from the obvious irrelevance of territorial contests at low density, selection alone has no preference for fecundity, competitive ability or longevity. One or both of the factors we set aside — pleiotropy/trade-offs and mutation bias — are needed to get true “primary strategy” trait differentiation.

Nevertheless, it is interesting to note that ruderals, which are typically thought of as high fecundity dispersers (*b*-specialists), may also be strongly *d*-selected, which while unintuitive, is consistent with our findings. An effective way to reduce *d* in the face of unavoidable physical destruction is to shorten the time to reproductive maturity — short life cycles are a characteristically ruderal trait. Moreover, a recent hierarchical cluster analysis of coral traits did find a distinct “ruderal” cluster, but high fecundity was not its distinguishing feature. Rather, ruderals used brood- (as opposed to broadcast-) spawning, which could plausibly be a mechanism for improving propagule survivorship in disturbed environments [Darling et al., 2012].

One potential limitation of our model as a general-purpose model of density-dependent selection is its restriction to interference competition between juveniles for durable resources (lottery recruitment to adulthood), analogous to the ubiquitous assumption of viability selection in population genetics [Ewens, 2004, p. 45]. In some respects this is the complement of consumable resource competition models, which restrict their attention to indirect exploitation competition, typically without age structure [Tilman, 1982]. In the particular case that consumable resources are spatially localized (e.g. due to restricted movement through soils), resource competition and territorial acquisition effectively coincide, and in principle resource competition could be represented by a competitive ability *c* (or conversely, *c* should be derivable from resource competition). The situation is more complicated if the resources are well-mixed, since, in general, resource levels then need to be explicitly tracked. It seems plausible that explicit resource tracking may not be necessary when the focus is on the evolution of similar genotypes that use identical resources rather than the stable co-existence of widely differing species with different resource preferences [Ram et al., 2016]. We are not aware of any attempts to delineate conditions under which explicit resource tracking is unnecessary even if it is assumed that community structure is ultimately

determined by competition for consumable resources. More work is needed connecting resource competition models to the density-dependent selection literature, since most of the former has to date been focused on narrower issues of the role of competition at low resource availability and in the absence of direct interactions between organisms at the same trophic level [Aerts, 1999, Davis et al., 1998, Tilman, 2007].

While our model can be applied to species rather than genotypes (e.g. ecological invasions), our focus is genotype evolution i.e. the change in allele frequencies over time. Our assumption that there are no large  $c$  discrepancies (section “Mean field approximation”) amounts to a restriction on the amount of genetic variation in  $c$  in the population. Since beneficial mutation effect sizes will typically not be much larger than a few percent, large  $c$  discrepancies can only arise if the mutation rate is extremely large, and so the assumption will not be violated in most cases. However, this restriction could become important when looking at species interactions rather than genotype evolution.

In the introduction we mentioned the recurring difficulties with confounding selection and demography in population genetic inference. It seems that Eq. (4) or something similar (and hopefully more analytically tractable) is unavoidable for the analysis of time-course genetic data because, fundamentally, selective births and deaths affect both abundances and frequencies, not one or the other in isolation. Moreover, some aspects of allele frequency change are intrinsically density-dependent. In the classic lottery model, which as we have seen is essentially the Wright-Fisher model with overlapping generations,  $b_i$  and  $c_i$  are equivalent in the sense that the number of territorial victories only depends on the product  $b_i c_i$  (see “Model”). This is no longer the case in our extension, where  $b$  and  $c$  specialists can co-exist. This “colonization-competition trade-off” is well known in the co-existence literature [Tilman, 1994]. It and similar forms of “spatial co-existence” in stable environments have previously been modeled either with Levin’s qualitative representation of competition [Levins and Culver, 1971, Tilman, 1994], as opposed to the quantitative  $c$  of lottery competition, or with a more sophisticated treatment of space (non-uniform dispersal; Bolker and Pacala 1999, Shmida and Ellner 1984). In cyclical environments,

polymorphisms can be stabilized by the bounded density effect, which is completely lost if there is an exclusive focus on allele frequencies [Yi and Dean, 2013]. We leave the details of how our model might be applied to inference problems, including the crucial issue of its genetic drift predictions (providing a null model for neutral sites), for future work.

## Appendix A: Poisson approximation

For simplicity of presentation, we have assumed a Poisson distribution for the  $x_i$  as our model of dispersal. Strictly speaking, the total number of  $i$  propagules  $\sum x_i$  (summed over unoccupied territories) is then no longer a constant  $m_i$ , but fluctuates between generations for a given mean  $m_i$ , which is more biologically realistic. Nevertheless, since we do not consider the random fluctuations in type abundances here, and for ease of comparison with the classic lottery model, we ignore the fluctuations in  $m_i$ . Instead we focus, on Poisson fluctuations in propagule composition in each territory.

In the exact model of random dispersal, the counts of a genotype's propagules across unoccupied territories follows a multinomial distribution with dimension  $U$ , total number of trials equal to  $m_i$ , and equal probabilities  $1/U$  for a propagule to land in a given territory. Thus, the  $x_i$  in different territories are not independent random variables. However, for sufficiently large  $U$  and  $m_i$ , this multinomial distribution for the  $x_i$  across territories is closely approximated by a product of independent Poisson distributions for each territory, each with rate parameter  $l_i$  [Arenbaev, 1977, Theorem 1]. Since we are ignoring finite population size effects, we effectively have  $T \rightarrow \infty$ , in which case  $U$  can be only be small enough to violate the Poisson approximation if there is vanishing population turnover, and then the dispersal distribution is irrelevant anyway. Likewise, in ignoring stochastic finite population size for the  $n_i$ , we have effectively already assumed that  $m_i$  is large enough to justify the Poisson approximation (the error scales as  $1/\sqrt{m_i}$ ; Arenbaev 1977).

## Appendix B: Derivation of growth equation

We separate the right hand side of Eq. (2) into three components  $\Delta_+ n_i = \Delta_u n_i + \Delta_r n_i + \Delta_a n_i$  which vary in relative magnitude depending on the propagule densities  $l_i$ . Following the notation in the main text, the Poisson distributions for the  $x_i$  (or some subset of the  $x_i$ ) will be denoted  $p$ , and we use  $P$  as a general shorthand for the probability of particular outcomes.

### Growth without competition

The first component,  $\Delta_u n_i$ , accounts for territories where only one focal propagule is present  $x_i = 1$  and  $x_j = 0$  for  $j \neq i$  ( $u$  stands for “uncontested”). The proportion of territories where this occurs is  $l_i e^{-L}$ , and so

$$\Delta_u n_i = U l_i e^{-L} = m_i e^{-L}. \quad (7)$$

### Competition when rare

The second component,  $\Delta_r n_i$ , accounts for territories where a single focal propagule is present along with at least one non-focal propagule ( $r$  stands for “rare”) i.e.  $x_i = 1$  and  $X_i \geq 1$  where  $X_i = \sum_{j \neq i} x_j$  is the number of nonfocal propagules. The number of territories where this occurs is  $U p_i(1)P(X_i \geq 1) = b_i n_i e^{-l_i}(1 - e^{-(L-l_i)})$ . Thus

$$\Delta_r n_i = m_i e^{-l_i}(1 - e^{-(L-l_i)}) \left\langle \frac{c_i}{c_i + \sum_{j \neq i} c_j x_j} \right\rangle_{\tilde{p}}, \quad (8)$$

where  $\langle \rangle_{\tilde{p}}$  denotes the expectation with respect to  $\tilde{p}$ , and  $\tilde{p}$  is the probability distribution of nonfocal propagule abundances  $x_j$  *after* dispersal, in those territories where exactly one focal propagule, and at least one non-focal propagule, landed.

Our “mean field” approximation is to replace  $x_j$  with its mean in the last term in Eq. (8),

$$\left\langle \frac{c_i}{c_i + \sum_{j \neq i} c_j x_j} \right\rangle_{\tilde{p}} \approx \frac{c_i}{c_i + \sum_{j \neq i} c_j \langle x_j \rangle_{\tilde{p}}}. \quad (9)$$

Below we justify this replacement by arguing that the standard deviation  $\sigma_{\tilde{p}}(\sum_{j \neq i} c_j x_j)$  (with respect to  $\tilde{p}$ ), is much smaller than  $\langle \sum_{j \neq i} c_j x_j \rangle_{\tilde{p}}$ .

We first calculate  $\langle x_j \rangle_{\tilde{p}}$ . Let  $X = \sum_j x_j$  denote the total number of propagules in a territory and  $\mathbf{x}_i = (x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_G)$  denote the vector of non-focal abundances, so that  $p(\mathbf{x}_i) = p_1(x_1) \dots p_{i-1}(x_{i-1}) p_{i+1}(x_{i+1}) \dots p_G(x_G)$ . Then,  $\tilde{p}$  can be written as

$$\begin{aligned} \tilde{p}(\mathbf{x}_i) &= p(\mathbf{x}_i | X \geq 2, x_i = 1) \\ &= \frac{P(\mathbf{x}_i, X \geq 2 | x_i = 1)}{P(X \geq 2)} \\ &= \frac{1}{1 - (1 + L)e^{-L}} \sum_{X=2}^{\infty} P(X) p(\mathbf{x}_i | X_i = X - 1), \end{aligned} \quad (10)$$

and so

$$\begin{aligned} \langle x_j \rangle_{\tilde{p}} &= \sum_{\mathbf{x}_i} \tilde{p}(\mathbf{x}_i) x_j \\ &= \frac{1}{1 - (1 + L)e^{-L}} \sum_{X=2}^{\infty} P(X) \sum_{\mathbf{x}_i} p(\mathbf{x}_i | X_i = X - 1) x_j. \end{aligned} \quad (11)$$

The inner sum over  $\mathbf{x}_i$  is the mean number of propagules of a given nonfocal type  $j$  that will be found in a territory which received  $X - 1$  nonfocal propagules in total, which is equal to  $\frac{l_j}{L - l_i}(X - 1)$ . Thus,

$$\begin{aligned} \langle x_j \rangle_{\tilde{p}} &= \frac{l_j}{1 - (1 + L)e^{-L}} \frac{1}{L - l_i} \sum_{X=2}^{\infty} P(X)(X - 1) \\ &= \frac{l_j}{1 - (1 + L)e^{-L}} \frac{L - 1 + e^{-L}}{L - l_i}, \end{aligned} \quad (12)$$

where the last line follows from  $\sum_{X=2}^{\infty} P(X)(X - 1) = \sum_{X=1}^{\infty} P(X)(X - 1) = \sum_{X=1}^{\infty} P(X)X - \sum_{X=1}^{\infty} P(X)$ .

The exact analysis of the fluctuations in  $\sum_{j \neq i} c_j x_j$  is complicated because the  $x_j$  are not independent with respect to  $\tilde{p}$ . These fluctuations are part of the “drift” in type abundances which we leave for future work. Here we use the following approximation to give some insight into the

magnitude of these fluctuations and also the nature of the correlations between the  $x_j$ . We replace  $\tilde{p}$  with  $\tilde{q}$ , defined as the  $\mathbf{x}_i$  Poisson dispersal probabilities conditional on  $X_i \geq 1$  (which are independent). The distinction between  $\tilde{p}$  with  $\tilde{q}$  will be discussed further below. The  $\tilde{q}$  approximation gives  $\langle x_j \rangle_{\tilde{q}} = \langle x_j \rangle_p / C = l_j / C$ ,

$$\begin{aligned}\sigma_{\tilde{q}}^2(x_j) &= \langle x_j^2 \rangle_{\tilde{q}} - \langle x_j \rangle_{\tilde{q}}^2 \\ &= \frac{1}{C} \langle x_j^2 \rangle_p - \frac{l_j^2}{C^2} \\ &= \frac{1}{C} (l_j^2 + l_j) - \frac{l_j^2}{C^2} \\ &= \frac{l_j^2}{C} \left(1 - \frac{1}{C}\right) + \frac{l_j}{C},\end{aligned}\tag{13}$$

and

$$\begin{aligned}\sigma_{\tilde{q}}(x_j, x_k) &= \langle x_j x_k \rangle_{\tilde{q}} - \langle x_j \rangle_{\tilde{q}} \langle x_k \rangle_{\tilde{q}} \\ &= \frac{1}{C} \langle x_j x_k \rangle_p - \frac{l_j l_k}{C^2} \\ &= \frac{l_j l_k}{C} \left(1 - \frac{1}{C}\right),\end{aligned}\tag{14}$$

503 where  $C = 1 - e^{-(L-l_i)}$  and  $j \neq k$ .

504 The exact distribution  $\tilde{p}$  assumes that exactly one of the propagules present in a given site  
505 after dispersal belongs to the focal type, whereas  $\tilde{q}$  assumes that there is a focal propagule  
506 present before non-focal dispersal commences. As a result,  $\tilde{q}$  predicts that the mean propagule  
507 density is greater than  $L$  (in sites with only one focal propagule is present) when the focal  
508 type is rare and the propagule density is high. This is erroneous, because the mean number  
509 of propagules in every site is  $L$  by definition. Specifically, if  $L - l_i \approx L \gg 1$ , then the mean  
510 propagule density predicted by  $\tilde{q}$  is approximately  $L + 1$ . The discrepancy causes rare invaders  
511 to have an intrinsic rarity disadvantage (territorial contests under  $\tilde{q}$  are more intense than they  
512 should be). In contrast, Eq. (12) correctly predicts that there are on average  $\sum_{j \neq i} \langle x_j \rangle_{\tilde{p}} \approx L - 1$

nonfocal propagules because  $\tilde{p}$  accounts for potentially large negative covariances between the  $x_j$  “after dispersal”. By neglecting the latter covariances,  $\tilde{q}$  overestimates the fluctuations in  $\sum_{j \neq i} c_j x_j$ ; thus  $\tilde{q}$  gives an upper bound on the fluctuations. The discrepancy between  $\tilde{q}$  and  $\tilde{p}$  will be largest when  $L$  is of order 1 or smaller, because then the propagule assumed to already be present under  $\tilde{q}$  is comparable to, or greater than, the entire propgaule density.

Decomposing the variance in  $\sum_{j \neq i} c_j x_j$ ,

$$\sigma_{\tilde{q}}^2(\sum_{j \neq i} c_j x_j) = \sum_{j \neq i} \left[ c_j^2 \sigma_{\tilde{q}}^2(x_j) + 2 \sum_{k > j, k \neq i} c_j c_k \sigma_{\tilde{q}}(x_j, x_k) \right], \quad (15)$$

and using the fact that  $\sigma_{\tilde{q}}(x_j, x_k)$  and the first term in Eq. (13) are negative because  $C < 1$ , we obtain an upper bound on the relative fluctuations in  $\sum_{j \neq i} c_j x_j$ ,

$$\frac{\sigma(\sum_{j \neq i} c_j x_j)}{\langle \sum_{j \neq i} c_j x_j \rangle} = C^{1/2} \frac{\left( \sum_{j \neq i} c_j^2 l_j + (1 - 1/C) \left( \sum_{j \neq i} c_j l_j \right)^2 \right)^{1/2}}{\sum_{j \neq i} c_j l_j} < C^{1/2} \frac{\left( \sum_{j \neq i} c_j^2 l_j \right)^{1/2}}{\sum_{j \neq i} c_j l_j}. \quad (16)$$

Suppose that the  $c_j$  are all of similar magnitude (their ratios are of order one). Then Eq. (16) is  $\ll 1$  for the case when  $L - l_i \ll 1$  (due to the factor of  $C^{1/2}$ ), and also for the case when at least some of the nonfocal propagule densities are large  $l_j \gg 1$  (since it is then of order  $1/\sqrt{L - l_i}$ ). The worst case scenario occurs when  $L - l_i$  is of order one. Then Eq. (16) gives a relative error of approximately 50%, which from our earlier discussion we know to be a substantial overestimate when  $L$  is of order 1. Our numerical results (Fig. 5) confirm that the relative errors are indeed small.

However, the relative fluctuations in  $\sum_{j \neq i} c_j x_j$  can be large if some of the  $c_j$  are much larger than the others. Specifically, in the presence of a rare, extremely strong competitor ( $c_j l_j \gg c_{j'} l_{j'}$  for all other nonfocal genotypes  $j'$ , and  $l_j \ll 1$ ), then the RHS of Eq. (16) can be large and we cannot make the replacement Eq. (9).

532 Substituting Eqs. (9) and (12) into Eq. (8), we obtain

$$\Delta_r n_i \approx m_i R_i \frac{c_i}{c}, \quad (17)$$

533 where  $R_i$  is defined in Eq. (5).

### 534 Competition when abundant

535 The final contribution,  $\Delta_a n_i$ , accounts for territories where two or more focal propagules are  
 536 present ( $a$  stands for “abundant”). Similarly to Eq. (8), we have

$$\Delta_a n_i = U(1 - (1 + l_i)e^{l_i}) \left\langle \frac{c_i x_i}{\sum_j c_j x_j} \right\rangle_{\hat{p}} \quad (18)$$

537 where  $\hat{p}$  is the probability distribution of both focal and nonfocal propagaule abundances *after*  
 538 dispersal in those territories where at least two focal propagules landed.

539 Again, we argue that the relative fluctuations in  $\sum c_j x_j$  are much smaller than 1 (with respect  
 540 to  $\hat{p}$ ), so that,

$$\left\langle \frac{c_i x_i}{\sum_j c_j x_j} \right\rangle_{\hat{p}} \approx \frac{c_i \langle x_i \rangle_{\hat{p}}}{\sum_j c_j \langle x_j \rangle_{\hat{p}}}. \quad (19)$$

Following a similar procedure as for  $\Delta_r n_i$ , where the vector of propagule abundances is denoted  $\mathbf{x}$ , the mean focal genotype abundance is,

$$\begin{aligned} \langle x_i \rangle_{\hat{p}} &= \sum_{\mathbf{x}} x_i p(\mathbf{x} | x_i \geq 2) \\ &= \sum_{x_i} x_i p(x_i | x_i \geq 2) \\ &= \frac{1}{1 - (1 + l_i)e^{-l_i}} \sum_{x_i \geq 2} p(x_i) x_i \\ &= l_i \frac{1 - e^{-l_i}}{1 - (1 + l_i)e^{-l_i}}. \end{aligned} \quad (20)$$

For nonfocal genotypes  $j \neq i$ , we have

$$\begin{aligned}
\langle x_j \rangle_{\hat{p}} &= \sum_{\mathbf{x}} x_j p(\mathbf{x} | x_i \geq 2) \\
&= \sum_X P(X | x_i \geq 2) \sum_{\mathbf{x}} x_j p(\mathbf{x} | x_i \geq 2, X) \\
&= \sum_X P(X | x_i \geq 2) \sum_{x_i} p(x_i | x_i \geq 2, X) \sum_{\mathbf{x}_i} x_j p(\mathbf{x}_i | X_i = X - x_i) \\
&= \sum_X P(X | x_i \geq 2) \sum_{x_i} p(x_i | x_i \geq 2, X) \frac{l_j(X - x_i)}{L - l_i} \\
&= \frac{l_j}{L - l_i} \left[ \sum_X P(X | x_i \geq 2) X - \sum_{x_i} p(x_i | x_i \geq 2) x_i \right] \\
&= \frac{l_j}{L - l_i} \left( L \frac{1 - e^{-L}}{1 - (1 + L)e^{-L}} - l_i \frac{1 - e^{-l_i}}{1 - (1 + l_i)e^{-l_i}} \right). \tag{21}
\end{aligned}$$

541 To calculate the relative fluctuations in  $\sum_{j \neq i} c_j x_j$ , we use a similar approximation as for  $\Delta_r n_i$ :  $\hat{p}$   
542 is approximated by  $\hat{q}$ , defined as the  $\mathbf{x}$  dispersal probabilities in a territory conditional on  $x_i > 2$   
543 (that is, treating the  $x_j$  as independent). All covariances between nonfocal genotypes are now zero,  
544 so that  $\sigma_{\hat{q}}^2(\sum c_j x_j) = \sum c_j^2 \sigma_{\hat{q}}^2(x_j)$ , where  $\sigma_{\hat{q}}^2(x_j) = l_j$  for  $j \neq i$ , and

$$\sigma_{\hat{q}}^2(x_i) = \frac{l_i}{D} \left( l_i + 1 - e^{-l_i} - \frac{l_i}{D} (1 - e^{-l_i})^2 \right), \tag{22}$$

545 where  $D = 1 - (1 + l_i)e^{-l_i}$ , and

$$\frac{\sigma_{\hat{q}}(\sum c_j x_j)}{\langle \sum c_j x_j \rangle} = \frac{\left( \sum_{j \neq i} c_j^2 l_j + c_i^2 \sigma_{\hat{q}}^2(x_i) \right)^{1/2}}{\sum_{j \neq i} c_j l_j + c_i l_i (1 - e^{-l_i}) / D}. \tag{23}$$

546 Similarly to Eq. (16), the RHS of Eq. (23) is  $\ll 1$  for the case that  $L \ll 1$  (due to a factor of  
547  $D^{1/2}$ ), and also for the case when at least some of the propagule densities (focal or nonfocal) are  
548 large — provided that  $c_i$  and the  $c_j$  are all of similar magnitude. Again, the worst case scenario  
549 occurs when  $l_i$  and  $L - l_i$  are of order 1, in which case Eq. (23) is around 35%, which is again  
550 where the  $\hat{q}$  approximation produces the biggest overestimate of the fluctuations in  $\mathbf{x}$ . Similarly

to Eq. (16), the RHS of (23) will not be  $\ll 1$  in the presence of a rare, extremely strong competitor.

Combining Eqs. (18) and (19), we obtain

$$\Delta_a n_i = m_i A_i \frac{c_i}{\bar{c}}, \quad (24)$$

where  $A_i$  is defined in Eq. (6).

## Comparison with simulations

Fig. 5 shows that Eq. (4) and its components closely approximate our density-dependent lottery model over a wide range of propagule densities (the latter is evaluated by direct simulations of uniform random dispersal and lottery competition). Two genotypes are present, one of which is at low frequency. The growth of the low-frequency genotype relies crucially on the low-density competition term  $R_i c_i / \bar{c}$ , and also to a lesser extent on the high density competition term  $A_i c_i / \bar{c}$  if  $l_1$  is large enough (Fig. 5b). On the other hand,  $R_i c_i / \bar{c}$  is negligible for the high-frequency genotype, which depends instead on high density territorial victories (Fig. 5d). Fig. 3 also shows the breakdown of the classic lottery model at low propagule densities.

## Appendix C: Mutant invasion under different environments

In this Appendix we evaluate the invasion of novel mutants in a population with a single resident type  $i$  (such that  $N = n_i$ ), which is in equilibrium.

For a single type  $i$  in equilibrium ( $\Delta n_i = 0$ ), we have  $R_i = 0$ ,  $\bar{c} = c_i$ ,  $A_i = (1 - (1 + L)e^{-L})/L$ , and Eq. (4) becomes

$$b_i(1 - e^{-L})/L - d_i = 0. \quad (25)$$

(Alternatively, Eq. (25) can be deduced directly from Eq. (2)). This implies  $L \approx b_i/d_i$  when  $b_i/d_i \gg 1$  and  $L \ll 1$  when  $b_i/d_i \approx 1$ . Now suppose that a novel mutant  $j$ , which is initially rare, appears in the population. Then  $A_j/R_j \ll 0$ ,  $l_j \approx 0$  and  $\bar{c} \approx c_i$ , and so, from Eq. (4), the mutant

Figure 3: The change in genotype abundances in a density dependent lottery model is closely approximated by Eq. (4).  $\Delta_+ n_i / m_i$  from Eq. (4) (and its separate components) are shown, along with direct simulations of random dispersal and lottery competition over one iteration over a range of propagule densities ( $U$  is varied between  $5 \times 10^3$  and  $10^6$  with  $m_1 = 10^4$  and  $m_2 = 9 \times 10^4$ ). Two genotypes are present. (a) and (b) show the low-frequency genotype with  $c$ -advantage ( $c_1 = 1.5$ ), (c) and (d) show the high-frequency predominant genotype ( $c_2 = 1$ ). Simulation points are almost invisible in (c) and (d) due to near exact agreement with Eq. (4). Dashed lines in (a) and (c) show the breakdown of the classic lottery model.

571 lineage's fitness is

$$\Delta n_j/n_j \approx b_j \left( e^{-L} + R_j \frac{c_j}{c_i} \right) - d_j \quad (26)$$

572 where  $R_j \approx (1 - e^{-L}) / \left( \frac{c_j}{c_i} + \frac{L-1+e^{-L}}{1-(1+L)e^{-L}} \right)$  since  $l_j \ll 1$ .

573 We now consider mutant invasion under the different environments from section "Primary  
574 strategies and Grime's triangle". In our representation of Grime's stressful environment,  $b \ll 1$ ,  
575  $d \approx b$  and  $L \ll 1$ , and so Eq. (26) becomes  $\Delta n_j/n_j \approx b_j - d_j$ . Mutations which improve  $b$  or  $d$  by  
576 the same fraction  $\epsilon$ , such that  $b_j = (1 + \epsilon)b_i$  or  $d_j = (1 - \epsilon)d_i$ , yield identical fitness benefits.

577 In our representation of Grime's ideal environment,  $d \ll 1$ ,  $b_i/d_i \gg 1$  and  $L \gg 1$ , and so Eq.  
578 (26) becomes

$$\Delta n_j/n_j \approx \frac{b_j}{c_j/c_i + L - 1} \frac{c_j}{c_i} - d_j \approx \frac{b_j}{L} \frac{c_j}{c_i} - d_j, \quad (27)$$

579 where the last approximation follows from the fact that  $c_j$  will be of similar magnitude to  $c_i$   
580 (ignoring mutations with very large effect sizes; incidentally, Eq. (1) yields the same expression  
581 by assuming  $L \rightarrow \infty$  even though this assumption is unrealistic for a rare mutant). Similarly to  
582 Grime's stressful environment, improving  $b$ ,  $c$ , or  $d$  by a fraction  $\epsilon$  yields identical fitness benefits,  
583 even though they may have very different absolute magnitudes, because the ancestral resident  
584 type's density-regulated birth rate  $b_i c_i / L$  exactly balances its mortality  $d_i$  in equilibrium. Biases  
585 in the direction of evolution of  $b$ ,  $c$  or  $d$  must again follow from biases in mutation availability  
586 or trade-offs/pleiotropy. The same argument applies for the high- $L$  interpretation of the stress  
587 regime.

588 To represent Grime's disturbed environment,  $\Delta_+ n_i$  is replaced with  $(1 - d_i)\Delta_+ n_i$ , and a single  
589 type reaches equilibrium when  $L/(1 - e^{-L}) = (1 - d_i)b_i/d_i$  (population persistence now requires  
590  $(1 - d_i)b_i > d_i$  rather than  $b_i > d_i$ ). We assumed  $d_i \approx 1$  and  $(1 - d_i)b_i \approx d_i$ , so that  $L \ll 1$ . A  
591 mutant's invasion fitness is then given by

$$\Delta n_j/n_j \approx (1 - d_j)b_j - d_j. \quad (28)$$

Another distinct feature of disturbed environments is that the bulk of mortality is environmental and unavoidable. That is,  $d_i = d_{ie} + d_{ig}$ , where the environmental part  $d_{ie}$  does not evolve, and the genetic part  $d_{ig}$  is affected proportionally by mutations  $d_{jg} = (1 - \epsilon)d_{ig}$ .

The effects of improving  $b$  and  $d$  are now no longer identical for given values of  $d_{ie}$  and  $d_{ig}$ . A  $b$ -mutation  $b_j = (1 + \epsilon)b_i$  gives  $\Delta n_j/n_j = \epsilon(1 - d_i)b_i \approx \epsilon d_i \approx \epsilon$ , whereas a  $d$ -mutation  $d_{jg} = (1 - \epsilon)d_{ig}$  gives  $\Delta n_j/n_j = \epsilon d_{ig}/(1 - d_i)$ . Since overall mortality is high ( $d_i \approx 1$ ),  $d_g$  can be small compared to  $d_e$  and yet still make a greater contribution to invasion fitness than  $b$ . The case where  $d_{ig}$  is so small that  $d_{ig} \ll 1 - d_i$  (i.e.  $d_{ig}$  is an order of magnitude smaller than  $1 - d_i$  which itself an order of magnitude smaller than  $d_{ie}$ ) effectively represents a hard constraint that  $d$  cannot evolve. We do not deny this possibility, but this brings us back to issues of mutational bias and constraint (the first two factors controlling the direction of evolution in section “Primary strategies and Grime’s triangle”), which we do not address in this manuscript.

Thus, assuming that  $d$  can evolve in this sense,  $d_{ig}$  is either comparable to or greater than  $1 - d_i$ . Yet  $d_{ig}$  cannot be appreciably greater than  $1 - d_i$  for long, because selection will then strongly favor reductions in  $d_g$  over increases in  $b$ , thereby bringing  $d_{ig}$  closer to  $1 - d_i$ . Thus, if  $b$  and  $d$  are subject to long-term evolution subject to external degradation at comparable rates [Bertram et al., 2017], then we expect selection on  $b$  and  $d$  to be of comparable strength in disturbed environments as well.

## Appendix D: Coexistence in a stable environment

To determine whether coexistence is possible in a constant environment, we check for “mutual invasion”, that is, we check that  $j$  will invade an  $i$ -dominated population, but  $i$  will also invade a  $j$ -dominated population.

We consider the case of coexistence between a  $b$ -specialist  $i$  and a  $c$ -specialist  $j$  ( $b_i > b_j$ ,  $c_j > c_i$  and  $d_i = d_j$ ). Suppose that  $b_i$  is so large that  $L \gg 1$  when  $i$  is dominant, and  $b_j$  is so small that  $L \ll 1$  when  $j$  is dominant. Then, when  $j$  is dominant, we have  $\Delta n_i/n_i = b_i - d_i = b_i - d_j = b_i - b_j > 0$ .

617 When  $i$  is dominant, Eq. (27) applies, where Eq. (25) implies  $d_j = d_i = b_i(1 - e^{-L})/L \approx b_i/L$ ,  
 618 and so

$$\Delta n_j/n_j \approx \frac{b_j c_j}{L c_i} - \frac{b_i}{L}. \quad (29)$$

619 Therefore, coexistence occurs if  $c_j/c_i$  is sufficiently large. The analogous argument for  $d$ - and  
 620  $c$ -specialists ( $d_i < d_j$  with  $L \gg 1$  when  $i$  dominates,  $L \ll 1$  when  $j$  dominates, and  $b_i = b_j$ ) gives  
 621  $\Delta n_j/n_j \approx d_i \frac{c_j}{c_i} - d_j$ , which again implies coexistence if  $c_j/c_i$  is sufficiently large.

622 For  $b$ -and  $d$ -specialists ( $c_i = c_j$ ), we have  $\Delta n_j/n_j \approx b_j d_i/b_i - d_j$  when  $i$  dominates and  
 623  $\Delta n_i/n_i \approx b_i d_j/b_j - d_i$  when  $j$  dominates. Thus, either  $i$  or  $j$  grows when rare, but not both,  
 624 and stable coexistence is not possible in a constant environment.
