1

Density-dependent selection and the limits of relative fitness

3 Abstract

[I'm going to revise this after your next round of comments] Selection is commonly described by assigning relative fitness values to genotypes. Yet when selection is strong, the ecological view of selection in density-regulated populations seems to be incompatible with constant-density relative fitnesses. Here we analyze the population ecological limits of relative fitness using a novel of density-dependent selection which contains a "reproductive excess. Our model clearly distinguishes between density-dependent selection and changes in density driven by selection. These two effects are confounded in standard models of 10 density-regulated population growth, but both are necessary, in combination with strong 11 selection, for relative fitness to break down in populations close to demographic equilibrium. Remarkably, both effects are not sufficient: we give an example of strong selection 13 on a density-regulating trait subject to density-dependent selection that conforms to the density-independent relative fitness description almost exactly. We reiterate the importance 15 of reproductive excesses in many species, which allows even strong selection to have no effect 16 on density. Our model also offers a possible alternative to relative fitness when the latter is 17 untenable, as is likely the case far from demographic equilibrium. (191 words)

20 Introduction

There are a variety of different measures of fitness. Some widely used examples are expected 21 lifetime reproductive ratio R_0 , intrinsic population growth rate r, equilibrium population 22 density/carrying capacity (often labeled "K") (Benton and Grant, 2000), and invasion fit-23 ness (Metz et al., 1992). In addition, "relative fitness" is the standard in much of evolutionary biology, particularly evolutionary genetics, where the focus is on relative genotypic propor-25 tions (Barton et al., 2007, pp. 468). The variety of fitness measures is not problematic in itself, because different measures have different uses. But it should be clear how these measures are connected to the processes of birth and death which ultimately drive selection 28 (Metcalf and Pavard, 2007; Doebeli et al., 2017). While such a connection is fairly clear 29 for absolute fitness measures like r or R_0 , relative fitness has only weak justification from 30 population ecology. It has even been proposed that relative fitness be justified from measure 31 theory, abandoning population biology altogether (Wagner, 2010). Given the ubiquitous use 32 of relative fitness, it is important that we understand its population ecological basis, both 33 to clarify its domain of applicability, and as part of the broader challenge of synthesizing 34 ecology and evolution. 35

For haploids growing in discrete time steps, the change in the abundance n_i of type i over a time step can be expressed as $\Delta n_i = (W_i - 1)n_i$ where W_i is absolute fitness. The corresponding change in frequency is $\Delta p_i = \left(\frac{W_i}{W} - 1\right)p_i$, where $\overline{W} = \sum_i W_i p_i$. In continuous time, the Malthusian parameter r_i replaces W_i and we have $\frac{dn_i}{dt} = r_i n_i$ and $\frac{dp_i}{dt} = (r_i - \overline{r})p_i$ (Crow et al., 1970, pp. 26). In the particular case that two types are present, a mutant labeled 1 and a wildtype labeled 2 for instance, then the continuous time equation for the mutant takes the familiar form

$$\frac{dp_1}{dt} = sp_1(1 - p_1),\tag{1}$$

where $s = r_1 - r_2$ is the selection coefficient. Note that in the discrete case we can replace the

 W_i with any set of values proportional to the W_i and the changes in frequency Δp_i will be unaffected. These values, which give no information about the dynamics of total population density $N = \sum_i n_i$, are called "relative fitnesses" (Barton et al., 2007, pp. 468). Similarly, the selection coefficient and frequency dynamics in Eq. (1) would be unaffected if we were to add an arbitrary constant to both r_1 and r_2 (these would be relative log fitnesses).

In the absence of crowding, each type grows exponentially at a constant "instrinsic" rate 49 r_i (for concreteness, we will primarily use Eq. (1) as our point of comparison but similar 50 logic applies in the discrete time case). The selection coefficient s is then a constant equal to 51 the difference in intrinsic population growth rates. The situation is more complicated when 52 we allow for population crowding. Since crowded and uncrowded conditions can favor quite 53 different traits (Travis et al., 2013), the Malthusian parameters r_i may respond differently 54 to changes in population density N, in which case the selection coefficient will be densitydependent. Eq. (1) would then need to supplemented with a model for the dynamics of Nto describe how the allele frequencies will change over time. The density and type frequency dynamics will in general be coupled (Travis et al., 2013). Thus, in a general crowded population the simple procedure of assigning constant relative fitness values to different types has to be replaced with an ecological description of absolute growth rates — a substantially more complicated problem. Note that frequency-dependent selection does not raise such a 61 severe problem, because we still only need to model the type frequencies, and not also the 62 ecological variable N. 63

In practice, many population genetics models assume that N has reached some fixed equilibrium value, and each type is assigned a constant relative fitness. Selection is typically assumed to operate through viability (e.g. Gillespie 2010, pp. 61), but other important population ecological assumptions — such as how density is regulated — are left unspecified. Beyond being conceptually unsatisfactory (Doebeli et al., 2017), we might also doubt whether this density-independent-s, constant-N setup is consistent with the ecology of many

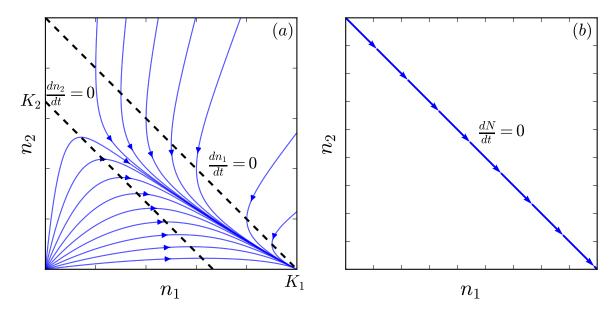

Figure 1: Selection in crowded environments shown as a phase diagram for the densities of two types n_1 and n_2 . (a) The logistic model $\frac{dn_1}{dt} = r_1(1 - \frac{n_1 + n_2}{K_1})n_1$ and $\frac{dn_2}{dt} = r_2(1 - \frac{n_1 + n_2}{K_2})n_1$ with $r_1 = r_2$ and $K_1 > K_2$. (b) The constant-N, relative fitness description of selection.

populations. Much of the seminal literature on density-dependent selection revolves around the connection between selection in crowded populations and the ability to keep growing at 71 higher densities (MacArthur and Wilson, 1967; Roughgarden, 1979). The classic example is 72 the logistic model, where the type with the greatest equilibrium population density "K" ex-73 cludes the others (Fig. 1a). Similarly, the " R^* rule", a central tenet of resource competition theory, states that when growth is limited by a single homogeneous consumable resource, the 75 type able to deplete the resource to the lowest equilibrium density R^* (which will often en-76 tail a different equilibrium population density) excludes the others (Grover, 1997). In these 77 examples, both N and s change during, and as a result of, adaptive sweeps. The Lotka-78 Volterra competition model also couples selection in crowded populations to density except 79 in special cases (Smouse, 1976; Mallet, 2012). It would therefore seem that the ubiquitous density-independent-s, constant-N description of selection is incompatible with a huge class of population ecological processes driving selection (Fig. 1b).

In light of this, and the related difficulties posed by frequency-dependent selection, rel-83 ative fitness values that are independent of type frequencies and population density are 84 typically justified as an approximation that holds when selection is weak (Kimura and Crow 1969; Ewens 2004, pp. 277; Charlesworth 1994, Chap. 4) and density is changing much 86 slower than type frequencies (Otto and Day, 2011, Fig. 9.5). Under these conditions, the 87 selection coefficient may depend on density and type frequencies, but since these change slowly the selection coefficient may remain approximately constant over several generations. In the case of density-dependence, this time interval of constancy could include entire selective sweeps. On the other hand, it is known in both simple models like the logistic (Kimura 91 and Crow, 1969), and in complex age-structured models (Charlesworth, 1994, Chap. 4), that frequency trajectories under strong density- or frequency-dependent selection can differ 93 substantially from the constant-s approximation.

Yet knowing that the constant-s approximation can fail in general when selection is 95 strong gives only a rough picture of the domain and manner in which the constant-s approximation breaks down. For instance, wild *Drosophila* is an important model system in 97 genetics, and exhibits strong seasonally-alternating selection in unison with large "boombust" density cycles (Messer et al., 2016; Bergland et al., 2014). Are we compelled to switch to a more ecologically-detailed evolutionary model based on Malthusian parameters or birth/death rates in this system? And if we make this switch, how much ecological detail do we need? Perhaps the strongest justification of constant relative fitness models is that 102 they are a powerful idealization. Thus, before abandoning them it is important to have 103 a better understanding when and how we should do so when selection is not weak, and 104 demography is not stable. 105

The rough picture given by the weak-selection approximation is missing at least one key element: virtually all models of density-dependent selection do not have a "reproductive excess" of juveniles that are more fragile than their adult counterparts (Turner and

Williamson, 1968; Kimura and Crow, 1969; Nei, 1971). Reproductive excesses allow selection to be concentrated at a juvenile "bottleneck", which means that the density of adults 110 can remain constant even if strong selection is occurring on juveniles — rather different 111 from the classic K-selection scenario. Although similar ideas featured prominently in early 112 debates on the regulation of population density (coincidentally grounded in experiments on 113 flies; Nicholson 1954), much of the reproductive excess literature revolves around Haldane's 114 "cost of selection" (Haldane, 1957), and is also poorly integrated with population ecology. 115 For instance, Kimura and Crow (1969) simply took constant N as a requirement and then 116 derived variants of the logistic model consistent with this. Nei (1971) proposed a model with 117 an explicit representation of reproductive excess, but used an unusual model of competition 118 based on pair-wise interactions which was only defined for at most two different types. As a 119 result, the role of reproductive excesses in justifying the use of constant relative finesses is 120 largely verbal. 121

Here we study the population ecology of relative fitness using a novel model of density-122 dependent population growth based on territorial contests. We restrict our attention to 123 asexual haploids with little or no age structure, since it is then easier to evaluate how 124 the success or failure of the constant-s description is tied to the underlying population 125 ecological assumptions. Our starting point is the classic lottery model which was developed by ecologists to study competition driven by territorial contests in reef fishes and plants (Sale, 127 1977; Chesson and Warner, 1981). The classic lottery incorporates a reproductive excess, 128 and fitness involves a product of fertility and juvenile viability akin to standard population 129 genetic models of selection (e.g. Crow et al. 1970, pp. 185). The classic lottery also assumes 130 constant N, and generations can overlap. Our first task is to generalize the lottery model 131 to create a variable-density lottery (sections "Model" and "Analytical approximation of the 132 variable-density lottery"). 133

Equipped with our new variable-density lottery model, we outline its selection properties

134

(section "Density-dependent selection in the variable-density lottery"). Next, we discuss selection on the ability to contest territories, which behaves like a pure constant-N, relative fitness trait, and discuss how this fits with the classical notion of K-selection (section "The response of density to selection; c-selection versus K-selection"). We then consider selection on density-regulating traits (section "Density-regulating traits and the threat of strong selection"), and conclude by contrasting the classical density-dependent selection literature with our results ("Discussion").

$_{^{142}}$ \mathbf{Model}

43 Assumptions and definitions

We assume that reproductively mature individuals ("adults") require their own territory to 144 survive and reproduce. All territories are identical, and the total number of territories is T. 145 Time advances in discrete iterations, each representing the time from birth to reproductive maturity. In a given iteration, the number of adults of the i'th type will be denoted by 147 n_i , the total number of adults by $N = \sum_i n_i$, and the number of unoccupied territories by U = T - N. We assume that the n_i are large enough that stochastic fluctuations in the n_i ("drift") can be ignored (with T also assumed large to allow for low type densities n_i/T). 150 Each iteration, adults produce propagules which disperse at random, independently of 151 distance from their parents, and independently of each other. We assume that each adult 152 from type i produces b_i propagules on average, so that the mean number of i propagules 153 dispersing to unoccupied territories is $m_i = b_i n_i U/T$. The parameter b_i can be thought of as a 154 measure of "colonization ability", which combines fecundity and dispersal ability (Levins and 155 Culver, 1971; Tilman, 1994). Random dispersal is then modeled using a Poisson distribution 156 $p_i(x_i) = l_i^{x_i} e^{-l_i}/x_i!$ for the number x_i of i propagates dispersing to any particular unoccupied 157 territory, where $l_i = m_i/U$ is the mean propagule density in unoccupied territories. The

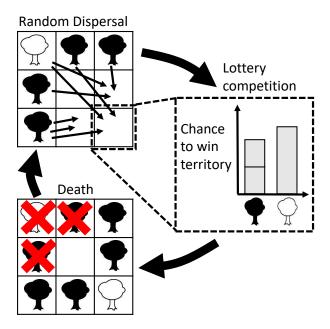

Figure 2: One iteration of our model. Propagules are dispersed by adults at random (only propagules landing on unoccupied territories are shown). Territories can receive zero propagules. Lottery competition then occurs in each territory that receives more than one propagule (only illustrated in one territory). In a given territory, each type has probability proportional to c_ix_i of winning the territory, where c_i measures competitive ability and x_i is the number of i propagules present. In the illustrated territory, more black propagules are present, but white is a stronger competitor and has a higher probability of winning. Territories are made available for the next iteration by the death of adults present at the start of the iteration (red crosses).

total propagule density will be denoted $L = \sum_{i} l_{i}$.

We assume that adults cannot be ousted by juveniles, so that recruitment to adulthood occurs exclusively in unoccupied territories. When multiple propagules land on the same unoccupied territory, the winner is determined by lottery competition: type i wins a territory with probability $c_i x_i / \sum_i c_i x_i$, where c_i is a constant representing relative competitive ability (Fig. 2). Since the expected fraction of unoccupied territories with propagule composition x_1, \ldots, x_G is $p_1(x_1) \cdots p_G(x_G)$ where G is the number of types present, and type i is expected to win a proportion $c_i x_i / \sum_i c_i x_i$ of these, type i's expected territorial acquisition is given by

$$\Delta_{+} n_{i} = U \sum_{x_{1}, \dots, x_{G}} \frac{c_{i} x_{i}}{\sum_{i} c_{i} x_{i}} p_{1}(x_{1}) \cdots p_{G}(x_{G}).$$
 (2)

Here the sum only includes territories with at least one propagule present. Since we do not consider drift here, we will not analyze the fluctuations around these two expectations.

Adult mortality only occurs in adults present at the start of the iteration, and at a constant, type-specific per-capita rate $0 \le d_i \le 1$ (Fig. 2). This gives an overall change in type abundances of

$$\Delta n_i = \Delta_+ n_i - d_i n_i. \tag{3}$$

172 Connection to the classic lottery model

In the classic lottery model (Chesson and Warner, 1981), unoccupied territories are assumed to be saturated with propagules from every type $(l_i \to \infty \text{ for all } i)$. From the law of large numbers, the composition of propagules in each territory will not deviate appreciably from the mean composition l_1, l_2, \ldots, l_G . Type i is thus expected to win a proportion $c_i l_i / \sum_i c_i l_i$ of the U available territories,

$$\Delta_{+} n_{i} = \frac{c_{i} l_{i}}{\sum_{i} c_{i} l_{i}} U = \frac{c_{i} l_{i}}{\overline{c} L} U, \tag{4}$$

where $\bar{c} = \sum_i c_i m_i / \sum_i m_i$ is the mean competitive ability for a randomly selected propagule.

Note that all unoccupied territories are filled in a single iteration of the classic lottery model,

whereas our more general model Eq. (2) allows for territories to be left unoccupied and hence

also accommodates low propagule densities.

Results

Analytical approximation of the variable-density lottery

Here we evaluate the expectation in Eq. (2) to better understand the dynamics of density-184 dependent lottery competition. Similarly to the classic lottery model, we replace the x_i , 185 which take different values in different territories, with "effective" mean values. However, 186 since we want to allow for low propagule densities, we cannot simply replace the x_i with 187 the means l_i as in the classic lottery. For a low density type, growth comes almost entirely 188 from territories with $x_i = 1$, for which its mean density $l_i \ll 1$ is not representative. We therefore separate Eq. (2) into $x_i = 1$ and $x_i > 1$ components, taking care to ensure that the 190 effective mean approximations for these components are consistent with each other (details in Appendix B). The resulting variable-density approximation only requires that there are 192 no large discrepancies in competitive ability (i.e. we do not have $c_i/c_j\gg 1$ for any two 193 types). We obtain 194

$$\Delta_{+} n_{i} \approx \left[e^{-L} + (R_{i} + A_{i}) \frac{c_{i}}{\overline{c}} \right] l_{i} U, \tag{5}$$

195 where

$$R_i = \frac{\overline{c}e^{-l_i}(1 - e^{-(L-l_i)})}{c_i + \frac{\overline{c}L - c_i l_i}{L - l_i} \frac{L - 1 + e^{-L}}{1 - (1 + L)e^{-L}}},$$

196 and

$$A_i = \frac{\overline{c}(1 - e^{-l_i})}{\frac{1 - e^{-l_i}}{1 - (1 + l_i)e^{-l_i}} c_i l_i + \frac{\overline{c}L - c_i l_i}{L - l_i} \left(L \frac{1 - e^{-L}}{1 - (1 + L)e^{-L}} - l_i \frac{1 - e^{-l_i}}{1 - (1 + l_i)e^{-l_i}} \right)}.$$

Comparing Eq. (5) to Eq. (4), the classic lottery per-propagate success rate $c_i/\bar{c}L$ has 197 been replaced by three separate terms. The first, e^{-L} , accounts for propagules which land 198 alone on unoccupied territories; these propagules secure the territories without contest. The 199 second, $R_i c_i/\bar{c}$, represents competitive victories on territories where only a single i propagule 200 lands, and at least one other propagule from a different type (this term dominates the 201 growth of a rare invader in a high density population and determines invasion fitness). The 202 third term, $A_i c_i/\bar{c}$, represents competitive victories in territories where two or more i type 203 propagules are present. The relative importance of these three terms varies with both the 204 overall propagule density L and the relative propagule frequencies l_i/L . If $l_i \gg 1$ for all 205 types, we recover the classic lottery model (only the $A_i c_i/\bar{c}$ term remains, and $A_i \to 1/L$). 206 Fig. 3 shows that Eq. (5) and its components closely approximate simulations of our 207 variable-density lottery model over a wide range of propagule densities. Two types are 208 present, one of which is at low frequency. The growth of the low-frequency type relies 209

In the special case that all types are competitively equivalent (identical c_i), Eq. (5) takes a simpler form,

also shows the breakdown of the classic lottery model at low propagule densities.

crucially on the low-density competition term $R_i c_i/\bar{c}$. On the other hand, $R_i c_i/\bar{c}$ is negligible

for the high-frequency type, which depends instead on high density territorial victories. Fig. 3

210

211

212

$$\Delta_{+}n_{i} = \frac{l_{i}}{L}(1 - e^{-L})U. \tag{6}$$

This formula can also be deduced directly from Eq. (2): $1 - e^{-L}$ is the fraction of territories that receive at least one propagule under Poisson dispersal, $(1 - e^{-L})U$ is the total number of such territories, and type i is expected to receive a fraction l_i/L of these. Total population density thus grows according to

$$\Delta N = (1 - e^{-L})U - \sum_{i} d_i n_i \tag{7}$$

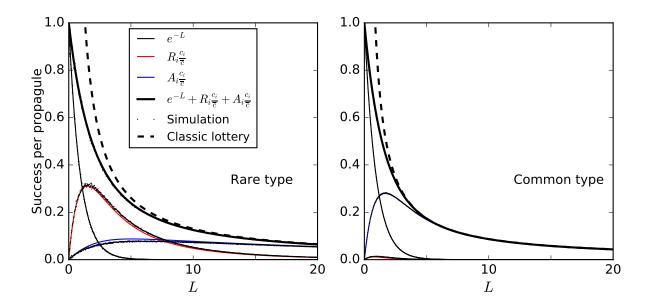

Figure 3: Comparison of Eq. (5), the classic lottery model, and simulations. The vertical axis is per-propagule success rate for all propagules $\Delta_+ n_i/m_i$, and for the three separate components in Eq. (5). Two types are present with $c_1 = 1$, $c_2 = 1.5$ and $l_2/l_1 = 0.1$. Simulations are conducted as follows: x_1, x_2 values are sampled $U = 10^5$ times from Poisson distributions with respective means l_1, l_2 , and the victorious type in each territory is then decided by random sampling weighted by the lottery win probabilities $c_i x_i/(c_1 x_1 + c_2 x_2)$. Simulation points are almost invisible for the common type due to near exact agreement with Eq. (5). Dashed lines show the failure of the classic lottery model at low density.

Density-dependent selection in the variable-density lottery

We now outline the basic properties of selection on b, c and d. The birth and mortality rates b and d are the traits which regulate density; b controls the fraction of unoccupied territories that are contested, while d controls adult mortality. Competitive ability c does not regulate density since it only affects the relative likelihood for each type to win a contested territory. Thus, selection between types which only differ in c occurs without causing N to change (Eq. (7) shows this formally).

Selection in the variable density lottery model is density-dependent, by which we mean 226 that the selection coefficient, measured by the difference in per-capita growth rate $\Delta n_i/n_i$ 227 between types, depends on N. Density-dependent selection is sometimes taken to mean a 228 qualitative change in which types are fitter than others at different densities (Travis et al., 229 2013). While reversal in the order of fitnesses and co-existence driven by density-regulation 230 are possible in the variable-density lottery (a special case of the competition-colonization 231 trade-off; Levins and Culver 1971; Tilman 1994; Bolker and Pacala 1999), questions related 232 to co-existence are tangential to our aims and will not be pursued further here. 233

Selection on c is density-dependent, with the strength of selection peaking at an intermediate density (Fig. 4). This intermediate peak occurs because at low density most territories are claimed without contest, whereas at high density few unoccupied territories are available to be contested. To see how selection on b and d depend on density, we write Eq. (6) in the alternative form

$$\frac{\Delta n_i}{n_i} = \frac{b_i}{\overline{b}} \frac{1 - e^{-\overline{b}N/T}}{N} (T - N) - d_i, \tag{8}$$

where we have used that fact that $L = \bar{b}N/T$, and \bar{b} is the population mean b. It is clear d-selection is independent of density. On the other hand, the strength of b-selection declines with density because the advantage of having greater b gets smaller the fewer territories there are to be claimed (Fig. 4).

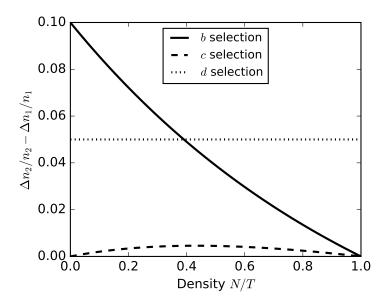

Figure 4: The density-dependence of selection in our variable-density lottery plotted as the difference in propagule success rate $\Delta n_2/m_2 - \Delta n_1/n_1$ between an adaptive variant 2 and a wildtype 1 with equal frequencies. Here $b_1 = 1$, $d_1 = 0.5$ and $c_1 = 1$. For b-selection we set $b_2 = b_1(1+\epsilon)$, and similarly for c and d, with $\epsilon = 0.1$. d-selection is density-independent, b-selection gets weaker with lower territorial availability, while c-selection initially increases with density as territorial contests become more important, but eventually also declines as available territories become scarce. The wildtype equilibrium density is $n_1/T \approx 0.4$.

The response of density to selection; c-selection versus K-selection

We now turn to the issue of how density responds to selection, comparing the variabledensity lottery and previous models of selection in density-regulated populations (Prout, 245 1980). Starting with some of the earliest work on the topic (Kostitzin, 1939; Christiansen, 246 2004), most previous models exhibit some form of "K-selection" i.e. selection in crowded 247 populations increases equilibrium density. This idea is intuitively appealing because births 248 balance deaths at equilibrium, and adaptive mutants must overcome the existing balance to 249 expand (Kostitzin, 1939, pp. 227). Yet, as we saw in the previous section, c-selection has no 250 effect on population density in the variable-density lottery. To make sense of how c-selection 251 fits with previous population growth models, we now revisit MacArthur's general treatment 252 of K-selection (MacArthur and Wilson, 1967). 253

MacArthur considered a population with two types that have densities n_1 and n_2 subject to density-dependent growth,

$$\frac{dn_1}{dt} = f_1(n_1, n_2) \qquad \frac{dn_2}{dt} = f_2(n_1, n_2). \tag{9}$$

The environment is assumed to remain constant apart from changing type densities. The functions f_1 and f_2 must decline to zero if n_1 or n_2 are sufficiently large, because the resources required for growth are limited. This defines nullclines $f_1(n_1, n_2) = 0$ and $f_2(n_1, n_2) = 0$ in (n_1, n_2) space. The outcome of selection is then determined by the relationship between these nullclines. Specifically, a type will be excluded if its nullcline is completely contained in the region bounded by the other type's nullcline. Thus, for a type to have the possibility of persisting, it must be able to keep growing to higher densities than the other type can tolerate in some region of (n_1, n_2) space (Fig. 1a).

MacArthur used "K" to label the four intersection points of the nullclines with the axes, specifically $f_1(K_{11}, 0) = 0$, $f_1(0, K_{12}) = 0$, $f_2(K_{21}, 0) = 0$ and $f_2(0, K_{22}) = 0$. These K values

determine whether a region of higher-density growth exists for each type, provided that the nullclines are close to being straight lines. Note that only K_{11} and K_{22} are equilibrium densities akin to the K parameter in the logistic model (Fig. 1a). The other intersection points, K_{12} and K_{21} , are related to competition between types. To be more concrete, in the Lotka-Volterra competition model we have

$$f_1(n_1, n_2) = r_1(1 - \alpha_{11}n_1 - \alpha_{12}n_2)n_1$$

$$f_2(n_1, n_2) = r_2(1 - \alpha_{22}n_1 - \alpha_{21}n_2)n_2$$
(10)

where $\alpha_{11} = 1/K_{11}$ and $\alpha_{22} = 1/K_{22}$ measure competitive effects within types, while $\alpha_{12} =$ $1/K_{12}$ and $\alpha_{21} = 1/K_{21}$ measure competitive effects between types. Hence, "fitness is K" 265 in crowded populations (MacArthur and Wilson, 1967, pp. 149) in the sense that selection 266 either favors the ability to keep growing at ever higher densities (moving a type's own nullcline 267 outwards), or the ability to suppress the growth of competitors at lower densities (moving 268 the nullcline of competitors inwards). This general idea is much broader than selection for 269 greater equilibrium density (Gill, 1974). 270 Compared to simple birth-death models (Kostitzin, 1939) or variants of the logistic 271 (Roughgarden, 1979), the Lotka-Volterra model clearly distinguishes between intra- and

(Roughgarden, 1979), the Lotka-Volterra model clearly distinguishes between intra- and inter-type competitive effects. Thus, one type can displace another without having a greater equilibrium density (Fig. 5a). Nevertheless, selection drives transient changes in density in the Lotka-Volterra model even if the initial and final densities of a sweep are the same (constant density only occurs for a highly restricted subset of r and α values; further details in Appendix C; also see Mallet 2012; Smouse 1976). Intuitively, for one type to exclude the other, competitive suppression of growth between types must be stronger than competitive suppression of growth within types, causing N to dip over a sweep (Fig. 5a).

By contrast, density trajectories for c-selection in the variable-density lottery converge

280

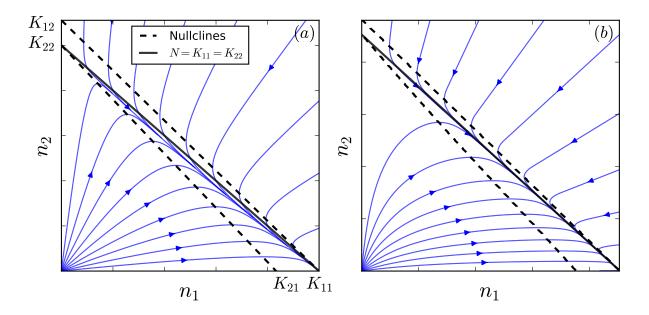

Figure 5: Selection between types with identical equilibrium density but different inter-type competitive ability. (a) Lotka-Volterra competition (Eq. 10) with $r_1 = r_2 = 1$, $\alpha_{11} = \alpha_{22} = 1$, $\alpha_{12} = 0.9$ and $\alpha_{21} = 1.2$. Trajectories do not follow the line $N = K_{11} = K_{22}$. (b) Lottery competition (Eq. 5) with $b_1 = b_2 = 5$, $d_1 = d_2 = 0.1$ and $c_1/c_2 = 5$. Trajectories converge on the line $N = K_{11} = K_{22}$.

on a line of constant equilibrium density (Fig. 5b). This means that once the population reaches demographic equilibrium, it behaves indistinguishably from a constant-N relative fitness model (Fig. 1b). This complete uncoupling of density from c-selection arises due to the presence of an excess of propagules which pay the cost of selection without affecting adult density. As a result, Eq. (1) holds in equilibrium even though c-selection is density-dependent.

Density-regulating traits and the threat of strong selection

The previous section underscores the fact that density must be affected by ongoing selection to threaten Eq. (1). We now turn to selection on density-regulating traits such as b and d in the variable density lottery.

As shown in Fig. 4, d-selection is independent of density; the selection coefficient for a d-variant with $d_2 = d_1(1 - \epsilon)$ is a constant $s = \epsilon d_1$. Thus, to threaten the assumption of density-independent s in an equilibrium population we require selection to act on a trait that is both density-dependent and density-regulating.

This is the case for b in the variable-density lottery. However, before we discuss this relatively complicated trait, it is helpful to summarize the threat to Eq. (1) in simpler models of density-regulated growth, as exemplified by the birth-death model (Kostitzin, 1939)

$$\frac{dn_i}{dt} = (b_i - \delta_i N)n_i. \tag{11}$$

Here δ_i is per-capita mortality due to crowding (for simplicity, there are no deaths when uncrowded). Starting from a type 1 population in equilibrium (we consider the non-equilibrium case in BLAH), a variant with $\delta_2 = \delta_1(1 - \epsilon)$ has density-dependent selection coefficient $s = \epsilon \delta_1 N$ in Eq. (1). This only affects the sweep if N changes substantially as the population shifts to the new equilibrium. From Eq. (11) we have $N_{\text{initial}} = b_1/\delta_1$ and

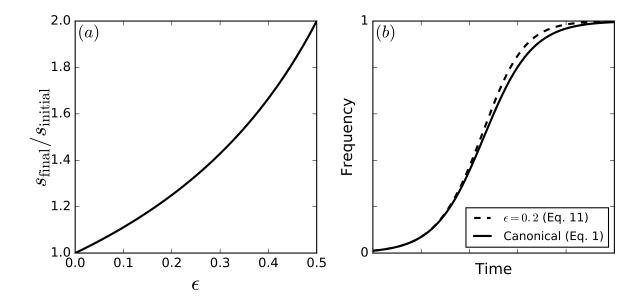

Figure 6: (a) Proportional change in the selection coefficient for a type that experiences proportionally $1 - \epsilon$ fewer deaths induced by crowding. The population is in demographic equilibrium at the start and end of the sweep. (b) Example equilibrium-to-equilibrium sweep.

 $N_{\text{final}} = b_1/(\delta_1(1-\epsilon)) = N_{\text{initial}}/(1-\epsilon)$, and so $s_{\text{initial}} = \epsilon b_1$ and $s_{\text{final}} = s_{\text{initial}}/(1-\epsilon)$. Consequently, substantial deviations from Eq. (1) occurs if there is sufficiently strong selection on δ (Fig. 6; Kimura and Crow 1969; Crow et al. 1970).

Equilibrium-to-equilibrium b-sweeps in the variable-density lottery are qualitatively dif-306 ferent from δ sweeps, because greater b not only means more propagules contesting territo-307 ries, but also more territories being contested. Together, the net density-dependent effect 308 on b-selection is zero; in Eq. (8), since $b_i/\bar{b}=1$ in a single-type equilibrium, the density-309 dependence factor $f(\overline{b}, N) = \frac{1 - e^{-\overline{b}N/T}}{N}(T - N)$ is exactly equal to the constant mortality rate 310 at the beginning and end of a b-sweep, even though b and density change. During the sweep 311 there is some deviation in $f(\bar{b}, N)$, but this deviation is an order of magnitude smaller than 312 for a δ sweep (the density-dependent deviation constant s in Fig. 6 is of order ϵ , whereas the 313 analogous effect for b sweep in the variable-density lottery is only of order ϵ^2 ; see Appendix 314 D for details). Since selection must already be strong for a δ -sweep to threaten Eq. (1), 315

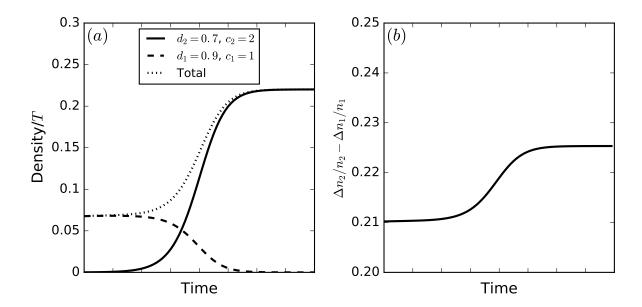

Figure 7: Simultaneous selection on d and c in the variable-density lottery model as predicted by Eq. (5). Selection is not constant over the sweep because d is density-regulating and c is density-dependent.

the density-independent model applies effectively exactly for equilibrium *b*-sweeps. Note, however, that the selection coefficient for *b*-sweeps (as defined by differences in $\Delta n_i/n_i$) does depend on frequency because of the $1/\bar{b}$ factor.

If selection acts simultaneously on more than one trait in the variable-density lottery, then evolution in a density-regulating trait can drive changes in the strength of selection on a trait subject to density-dependent selection (Fig. 7). This can produce behavior analogous to selection on δ in Fig. 6.

3 Discussion

Summarizing the three traits in the variable-density lottery model: (i) c-selection is densitydependent, but c does not regulate density; (ii) d regulates density, but d-selection is densityindependent; (iii) b regulates density and b-selection is density-dependent. Yet despite these

differences, pure b, c and d sweeps starting and ending at equilibrium all obey the densityindependent relative fitness description of selection almost exactly. This behavior is quite
different from that found in the classical density-dependent selection literature (Roughgarden, 1979; Christiansen, 2004).

To briefly review: based on a diploid, bi-allelic variant of the logistic model, the r/K331 scheme proposed a dichotomy between r-selection (uncrowded) and K-selection (crowded) 332 (MacArthur, 1962), with the latter taken to mean selection for greater equilibrium density 333 (Gill, 1974). A more general Lotka-Volterra model introduces the inter-type α_{ij} competition 334 coefficients, with selection on these termed " α -selection" (Gill, 1974; Joshi et al., 2001). 335 Setting aside r which confers no selective advantage at equilibrium, we are left with K 336 and α , which both behave like δ in Eq. (11) in that they are density-dependent and cause 337 density to change over a sweep (although N only dips transiently during an α -sweep). Thus, 338 strong selection is sufficient for relative fitness to break down in the classical view of density-339 dependent selection. 340

Our variable-density lottery model shows that it is not simply a lack of ecological realism that underlies the contrast between relative fitness and the classical view of densitydependent selection. Rather, in many population growth models, only one life-history stage
is represented, and the competitive effects resulting from crowding appear as a reduction in
absolute fitness that only depends on the type densities at this life-history stage (e.g. the n_i^2 and $n_i n_j$ terms in the Lotka Volterra equation). As noted in the introduction, this precludes selection concentrated at a fragile juvenile stage as a result of a reproductive excess
(Chesson, 1983; Turner and Williamson, 1968; Kimura and Crow, 1969; Nei, 1971).

Reproductive excesses appear in the variable-density lottery model when the number of propagules is greater than the number of available territories. Then only $\approx 1/L$ of the juveniles contesting available territories survive to adulthood. Unlike the role of adult density n_i in single-life-stage models, it is the propagule densities l_i that represent the crowding

that drives competition (a "critical age-group"; Charlesworth 1994, pp. 54). In general, reproductive excesses will tend to produce strictly-relative lottery-type contests in which 354 fitter types grow at the expense of others by preferentially filling the available adult "slots". 355 The number of slots can remain fixed or change independently of selection at the juvenile 356 stage. By ignoring reproductive excesses, single life-stage models are biased to have total 357 population density be sensitive to ongoing selection. In this respect, the viability selection 358 heuristics that are common in population genetics (Gillespie, 2010, pp. 61) actually capture 359 an important ecological process without jumping to the full complexity of age-structured 360 models. 361

We now turn to the breakdown of the density-independent relative fitness assumption 362 which occurs when strong selection changes population density and is also density-dependent 363 (Fig. 6). In the variable-density lottery, this occurs if and only if types differ in more than one 364 trait (Fig. 7). The c and d traits represent the two distinct directions in which density and 365 selection interact: selection may depend on density, and density may depend on selection (Prout, 1980). The combination is necessary to pose a threat to Eq. (1). However, the 367 b trait remarkably demonstrates that the combination is not sufficient, since the density-368 dependence of b-selection disappears over equilibrium-to-equilibrium b-sweeps. Thus, the simple differential/difference equations that have become standard in discussions of densitydependent selection (Roughgarden, 1979; Christiansen, 2004; Mallet, 2012; Travis et al., 2013) actually represent a confounded form of the interaction between density and selection. 372 While this is a conceptual reason to be wary of the classical density-dependent selection 373 models, it is not clear what trait variation to expect in nature. Should we expect muta-374 tions to generally affect b, c and d independently of each other, or pleiotropically such that 375 δ -like selection is prevalent? In the case of well-mixed indirect exploitation competition for 376 consumable resources, the R^* rule suggests that δ -like selection will be prevalent. However, 377 for many populations consumable resources are not well-mixed. Spatial localization of consumable resources (e.g. due to restricted movement of nutrients through soils) will tend to create a territorial situation similar to the lottery model, where resource competition only occurs locally and both it and interference competition are subsumed into the competitive ability c, which does not affect N.

The above findings underscore that the most serious threat to relative fitness arises from 383 deviations from demographic equilibrium. This can dramatically alter frequency trajectories 384 for individual sweeps (e.g. Fig. 9.5 in Otto and Day (2011); Fig. 5 in Mallet (2012)), as well 385 as the long-term outcomes of selection in fluctuating environments (Lande et al., 2009). This 386 would suggest that in the wild *Drosophila* example mentioned in the Introduction, there is 387 indeed no choice but to abandon relative fitness. The variable-density lottery could provide a 388 useful starting point for analyzing evolution in this and other far-from-equilibrium situations. 389 One convenient feature of our variable-density lottery (and lottery models in general) is a 390 formal similarity to the Wright-Fisher model, which should facilitate the analysis of "density-391 dependent drift". 392

Another issue with the constant-N relative fitness description of selection is that it precludes consideration of longer-term aspects of the interplay between evolution and ecology
such as population extinction. A variety of approaches have been developed for dealing with
these issues in quantitative genetics (Burger and Lynch, 1995; Engen et al., 2013), population genetics (Bertram et al., 2017) and adaptive dynamics (Ferriere and Legendre, 2013;
Dieckmann and Ferrière, 2004). Although density-dependent selection is pertinent to these
longer-term issues (Travis et al., 2013), our focus here has been the description of the timedependent process by which selection changes allele frequencies. This is particularly critical
for making sense of evolution at the genetic level, for which we now have abundant data.

492 Appendix A: Growth equation derivation

In this appendix we derive Eq. (5). Following the notation in the main text, the Poisson distributions for the x_i (or some subset of the x_i) will be denoted p, and we use P as a general shorthand for the probability of particular outcomes.

We start by separating the right hand side of Eq. (2) into three components

$$\Delta_{+}n_{i} = \Delta_{u}n_{i} + \Delta_{r}n_{i} + \Delta_{a}n_{i}, \tag{12}$$

which vary in relative magnitude depending on the propagule densities l_i . The first component, $\Delta_u n_i$, accounts for territories where only one focal propagule is present ($x_i = 1$ and $x_j = 0$ for $j \neq i$; u stands for "uncontested"). The proportion of territories where this occurs is $l_i e^{-L}$, and so

$$\Delta_u n_i = U l_i e^{-L} = m_i e^{-L}. \tag{13}$$

The second component, $\Delta_r n_i$, accounts for territories where a single focal propagule is present along with at least one non-focal propagule $(x_i = 1 \text{ and } X_i \ge 1 \text{ where } X_i = \sum_{j \ne i} x_j$ is the number of nonfocal propagules; r stands for "rare"). The number of territories where this occurs is $Up_i(1)P(X_i \ge 1) = m_i e^{-l_i}(1 - e^{-(L-l_i)})$. Thus

$$\Delta_r n_i = m_i e^{-l_i} \left(1 - e^{-(L-l_i)}\right) \left\langle \frac{c_i}{c_i + \sum_{j \neq i} c_j x_j} \right\rangle_{\tilde{p}}, \tag{14}$$

where $\langle \rangle_{\tilde{p}}$ denotes the expectation with respect to the probability distribution \tilde{p} of nonfocal

propagule abundances x_j , in those territories where exactly one focal propagule, and at least one non-focal propagule, landed.

The final contribution, $\Delta_a n_i$, accounts for territories where two or more focal propagules are present $(x_i \ge 2; a \text{ stands for "abundant"})$. Similar to Eq. (14), we have

$$\Delta_a n_i = U(1 - (1 + l_i)e^{-l_i}) \left\langle \frac{c_i x_i}{\sum_j c_j x_j} \right\rangle_{\hat{p}}$$
(15)

where \hat{p} is the probability distribution of both focal and nonfocal propagule abundances in those territories where at least two focal propagules landed.

To derive Eq. (5) we approximate the expectations in Eq. (14) and Eq. (15) by replacing x_i and the x_j with "effective" mean values as follows

$$\left\langle \frac{c_i}{c_i + \sum_{j \neq i} c_j x_j} \right\rangle_{\tilde{p}} \approx \frac{c_i}{c_i + \sum_{j \neq i} c_j \langle x_j \rangle_{\tilde{q}}}.$$
 (16)

$$\left\langle \frac{c_i x_i}{\sum_j c_j x_j} \right\rangle_{\hat{p}} \approx \frac{c_i \langle x_i \rangle_{\hat{q}}}{\sum_j c_j \langle x_j \rangle_{\hat{q}}}.$$
 (17)

Here the effective means $\langle \rangle_{\tilde{q}}$ and $\langle \rangle_{\hat{q}}$ are taken with respect to new distributions \tilde{q} and \hat{q} , respectively. In the following subsection we define \tilde{q} and \hat{q} and explain our reasoning for using these distributions to take the effective means.

The effective distributions \widetilde{q} and \widehat{q}

514

The approximations (16) and (17) must be consistent between rare and common types. To illustrate, suppose that two identical types (same b, c and d) are present, with low $l_1 \ll 1$ and high density $l_2 \approx L \gg 1$ respectively. Since L is large, uncontested territories make up a negligible fraction of the total. The rare type grows almost entirely due to $\Delta_r n_1$, while the common type grows almost entirely due to $\Delta_a n_2$. To ensure consistency, the ap-

proximate per-capita growth rates implied by the approximations (16) and (17) must be equal $\Delta_r n_1/m_1 = \Delta_a n_2/m_2$. Even small violations of this consistency condition would mean exponential growth of one type relative to the other. This behavior is clearly pathological, because any single-type population can be arbitrarily partitioned into identical rare and common subtypes. Thus, predicted growth or decline would depend on an arbitrary assignment of rarity.

For example, suppose that we use \tilde{p} and \hat{p} to calculate the effective means. The right hand side of Eq. (16) is then approximately 1/(L+1), and since $l_1 \ll 1$ and $L \gg 1$ we have $\Delta_r n_1 \approx 1/(L+1)$ in Eq. (14). Similarly, for the common type, $\sum_j \langle x_j \rangle_{\hat{p}} = L$ in Eq. (17), and so $\Delta_a n_2 \approx 1/L$. Thus, the identical rare type is pathologically predicted to decline in frequency.

The effective distributions \tilde{q} and \hat{q} are devised to avoid this pathology. The idea is to make the approximation that the distribution for the total number of propagules per territory is the same in all territories. This is only an approximation because conditioning on focal propagules being present does change the distribution of X in the corresponding subset of territories (in the above example, the mean propagule density across all territories is L, but in the territories responsible for the growth of the rare type we have $\langle X \rangle_{\tilde{p}} = L + 1$).

More formally, let \mathbf{x} denote the vector of propagule abundances (x_1, \ldots, x_G) in a given territory, and $\mathbf{x}_i = (x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_G)$ similarly denote the vector of non-focal abundances, so that $p(\mathbf{x}_i) = p_1(x_1) \cdots p_{i-1}(x_{i-1}) p_{i+1}(x_{i+1}) \cdots p_G(x_G)$. The corresponding total propagule numbers are denoted $X = \sum_j x_j$ and $X_i = X - x_i$. Then, in territories where one focal propagule and at least one non-focal propagule are present, the effective distribution is defined by

$$\tilde{q}(\mathbf{x}_i) = \sum_{X=2}^{\infty} P(X|X \ge 2) p(\mathbf{x}_i|X_i = X - 1), \tag{18}$$

where the total number of propagules X follows a Poisson distribution with mean L, and

 $P(X|X \ge 2) = P(X)/P(X \ge 2) = P(X)/(1 - (1 + L)e^{-L})$. Similarly, in territories where more than one focal propagule is present, the effective distribution is defined by

$$\hat{q}(\mathbf{x}) = \sum_{X=2}^{\infty} P(X|X \ge 2)p(\mathbf{x}|x_i \ge 2, X). \tag{19}$$

$_{\scriptscriptstyle{550}}$ Calculating the effective means

Here we calculate the effective means, starting with the $\Delta_r n_i$ component. We have

$$\langle x_j \rangle_{\tilde{q}} = \sum_{\mathbf{x}_i} \tilde{q}(\mathbf{x}_i) x_j$$

$$= \frac{1}{1 - (1 + L)e^{-L}} \sum_{X=2}^{\infty} P(X) \sum_{\mathbf{x}_i} p(\mathbf{x}_i | X_i = X - 1) x_j. \tag{20}$$

The inner sum over \mathbf{x}_i is the mean number of propagules of a given nonfocal type j that will be found in a territory which received X-1 nonfocal propagules in total, which is equal to $\frac{l_j}{L-l_i}(X-1)$. Thus,

$$\langle x_j \rangle_{\tilde{q}} = \frac{l_j}{1 - (1 + L)e^{-L}} \frac{1}{L - l_i} \sum_{X=2}^{\infty} P(X)(X - 1)$$

$$= \frac{l_j}{1 - (1 + L)e^{-L}} \frac{L - 1 + e^{-L}}{L - l_i},$$
(21)

where the last line follows from $\sum_{X=2}^{\infty} P(X)(X-1) = \sum_{X=1}^{\infty} P(X)(X-1) = \sum_{X=1}^{\infty} P(X)X - \sum_{X=1}^{\infty} P(X)$. Substituting Eqs. (16) and (21) into Eq. (14), we obtain

$$\Delta_r n_i \approx m_i R_i \frac{c_i}{\overline{c}},\tag{22}$$

where R_i is defined in Eq. (6).

Turning now to the $\Delta_a n_i$ component, the mean focal abundance is

$$\langle x_i \rangle_{\hat{q}} = \sum_{\mathbf{x}} \hat{q}(\mathbf{x}) x_i$$

$$= \sum_{x_i} p(x_i | x_i \ge 2) x_i$$

$$= \frac{1}{1 - (1 + l_i)e^{-l_i}} \sum_{x_i \ge 2} p(x_i) x_i$$

$$= l_i \frac{1 - e^{-l_i}}{1 - (1 + l_i)e^{-l_i}}.$$
(23)

For nonfocal types $j \neq i$, we have

$$\langle x_{j} \rangle_{\hat{q}} = \sum_{X=2}^{\infty} P(X|X \ge 2) \sum_{\mathbf{x}} p(\mathbf{x}|x_{i} \ge 2, X) x_{j}$$

$$= \sum_{X=2}^{\infty} P(X|X \ge 2) \sum_{x_{i}} p(x_{i}|x_{i} \ge 2, X) \sum_{\mathbf{x}_{i}} p(\mathbf{x}_{i}|X_{i} = X - x_{i}) x_{j}$$

$$= \sum_{X=2}^{\infty} P(X|X \ge 2) \sum_{x_{i}} p(x_{i}|x_{i} \ge 2, X) \frac{l_{j}(X - x_{i})}{L - l_{i}}$$

$$= \frac{l_{j}}{L - l_{i}} \left[\sum_{X=2}^{\infty} P(X|X \ge 2) X - \sum_{x_{i}} p(x_{i}|x_{i} \ge 2) x_{i} \right]$$

$$= \frac{l_{j}}{L - l_{i}} \left(L \frac{1 - e^{-L}}{1 - (1 + L)e^{-L}} - l_{i} \frac{1 - e^{-l_{i}}}{1 - (1 + l_{i})e^{-l_{i}}} \right). \tag{24}$$

In going from line 2 to 3, we used the same logic used to evaluate the inner sum in Eq. (20), and in going from 3 to 4 we have separately evaluated the contributions from the X and x_i terms in the numerator. Combining these results with Eqs. (15) and (17), we obtain

$$\Delta_a n_i = m_i A_i \frac{c_i}{\overline{c}},\tag{25}$$

where A_i is defined in Eq. (6).

558 Approximation limits

Eq. (16) and (17) must not only be consistent with each other, they must also be individually good approximations. Here we evaluate these approximations.

The fundamental requirement for making the replacement in Eqs. (16) and (17) is that we can ignore the fluctuations in the x_i and hence replace them with a constant effective mean value. Mathematically, we require that the standard deviations $\sigma_{\tilde{q}}(\sum_{j\neq i}c_jx_j)$ and $\sigma_{\hat{q}}(\sum_{j}c_jx_j)$ must be sufficiently small compared to the corresponding means $\langle \sum_{j\neq i}c_jx_j\rangle_{\tilde{q}}$ and $\langle \sum_{j}c_jx_j\rangle_{\hat{q}}$ in Eqs. (16) and (17) respectively.

To evaluate these standard deviations, we will work with \tilde{p} and \hat{p} distributions instead of \tilde{q} and \hat{q} . This is mathematically much simpler because the x_i are independent under \tilde{p} and \hat{p} , and is justified by the fact that \tilde{p} and \hat{p} are closely related to \tilde{q} and \hat{q} respectively, and so we expect the relevant means and standard deviations will be similar.

Starting with Eq. (16), we have $\langle x_j \rangle_{\tilde{p}} = l_j/C$, where $C = 1 - e^{-(L-l_i)}$, and the corresponding variances and covariances are given by

$$\sigma_{\tilde{p}}^{2}(x_{j}) = \langle x_{j}^{2} \rangle_{\tilde{p}} - \langle x_{j} \rangle_{\tilde{p}}^{2}$$

$$= \frac{l_{j}^{2} + l_{j}}{C} - \frac{l_{j}^{2}}{C^{2}}$$

$$= \left(1 - \frac{1}{C}\right) \frac{l_{j}^{2}}{C} + \frac{l_{j}}{C}, \tag{26}$$

and

$$\sigma_{\tilde{p}}(x_{j}, x_{k}) = \langle x_{j} x_{k} \rangle_{\tilde{p}} - \langle x_{j} \rangle_{\tilde{p}} \langle x_{k} \rangle_{\tilde{p}}$$

$$= \frac{1}{C} \langle x_{j} x_{k} \rangle_{p} - \frac{l_{j} l_{k}}{C^{2}}$$

$$= \left(1 - \frac{1}{C}\right) \frac{l_{j} l_{k}}{C} \qquad j \neq k. \tag{27}$$

Note that 1-1/C is negative because C<1. Decomposing the variance in $\sum_{j\neq i} c_j x_j$,

$$\sigma_{\tilde{p}}^2(\sum_{j\neq i} c_j x_j) = \sum_{j\neq i} \left[c_j^2 \sigma_{\tilde{p}}^2(x_j) + 2 \sum_{k>j, k\neq i} c_j c_k \sigma_{\tilde{p}}(x_j, x_k) \right], \tag{28}$$

we obtain

$$\frac{\sigma(\sum_{j\neq i} c_j x_j)}{\langle \sum_{j\neq i} c_j x_j \rangle} = C^{1/2} \frac{\left(\sum_{j\neq i} c_j^2 l_j + (1 - \frac{1}{C}) \left(\sum_{j\neq i} c_j l_j\right)^2\right)^{1/2}}{\sum_{j\neq i} c_j l_j}.$$
 (29)

Eq. (29) reveals two key points. First, when the c_j have similar magnitudes (their ratios 572 are of order one), Eq. (16) is an excellent approximation. In this case, the right hand side of 573 Eq. (29) is approximately equal to $C^{1/2} \left(\frac{1}{L-l_i} + 1 - \frac{1}{C} \right)^{1/2}$, which is small for both low and 574 high nonfocal densities. The worst case scenario occurs when $L - l_i$ is of order one, and it 575 can be directly verified that Eq. (16) is then still a good approximation (see Fig. 8). Second, 576 if some of the c_j are much larger than the others, the relative fluctuations in $\sum_{j\neq i} c_j x_j$ can 577 be large. Specifically, in the presence of a rare, strong competitor $(c_j l_j \gg c_{j'} l_{j'})$ for all other 578 nonfocal types j', and $l_j \ll 1$), then the right hand side of Eq. (29) can be large and we cannot make the replacement Eq. (16). Fig. 8 shows the breakdown of the effective mean approximation when the are large differences in c. 581

Turning now to Eq. (17), all covariances between nonfocal types are now zero, so that $\sigma_{\hat{p}}^2(\sum c_j x_j) = \sum c_j^2 \sigma_{\hat{p}}^2(x_j), \text{ where } \sigma_{\hat{p}}^2(x_j) = l_j \text{ for } j \neq i. \text{ Here}$

$$\sigma_{\hat{p}}^{2}(x_{i}) = \frac{l_{i}}{D} \left(l_{i} + 1 - e^{-l_{i}} - \frac{l_{i}}{D} \left(1 - e^{-l_{i}} \right)^{2} \right), \tag{30}$$

where $D = 1 - (1 + l_i)e^{-l_i}$, and

$$\frac{\sigma_{\hat{p}}(\sum c_j x_j)}{\langle \sum c_j x_j \rangle} = \frac{\left(\sum_{j \neq i} c_j^2 l_j + c_i^2 \sigma_{\hat{p}}^2(x_i)\right)^{1/2}}{\sum_{j \neq i} c_j l_j + c_i l_i (1 - e^{-l_i})/D}.$$
(31)

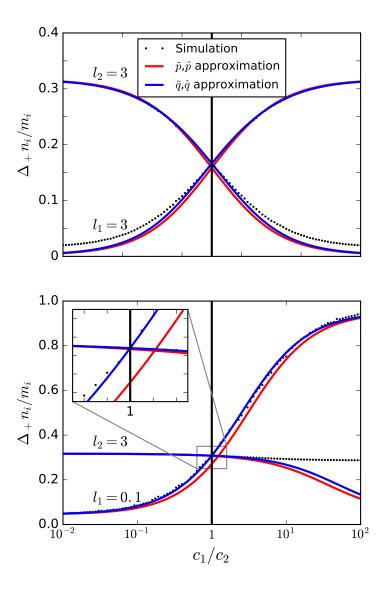

Figure 8: Comparison of our \tilde{q},\hat{q} approximation with simulations, and also with the naive \tilde{p},\hat{p} approximation, as a function of the relative c difference between two types. Our approximation breaks down in the presence of large c differences. The inset shows the pathology of the \tilde{p},\hat{p} approximation — growth rates are not equal in the neutral case c=1. Simulation procedure is the same as in Fig. 3, with $U=10^5$.

Similarly to Eq. (29), the right hand side of Eq. (31) is small for both low and high nonfocal densities. Again, the worst case scenario occurs when l_i and $L - l_i$ are of order 1, but Eq. (17) is still a good approximation in this case. Again, the approximation breaks down in the presence of a rare, strong competitor (Fig. 8).

Appendix B: Total density in the Lotka-Volterra competition model $\mathbf{p}_{\mathbf{p}}$

Here we show that under the Lotka-Volterra model of competition, total density N does not in general remain constant over a selective sweep in a crowded population even if the types have the same equilibrium density (for a related discussion on the density- and frequencydependence of selection in the Lotka-Volterra model, see (Smouse, 1976; Mallet, 2012)).

We assume equal effects of crowding within types $\alpha_{11} = \alpha_{22} = \alpha_{\text{intra}}$ and $N = 1/\alpha_{\text{intra}}$ and check whether it is then possible for $\frac{dN}{dt}$ to be zero in the sweep $(n_1, n_2 \neq 0)$. Substituting these conditions into Eq. (10), we obtain

$$\frac{dn_1}{dt} = r_1(\alpha_{11} - \alpha_{12})n_1n_2
\frac{dn_2}{dt} = r_2(\alpha_{22} - \alpha_{21})n_1n_2$$
(32)

Adding these together, $\frac{dN}{dt}$ can only be zero if

$$r_1(\alpha_{\text{intra}} - \alpha_{12}) + r_2(\alpha_{\text{intra}} - \alpha_{21}) = 0.$$
 (33)

To get some intuition for Eq. (33), suppose that a mutant arises with improved competitive ability but identical intrinsic growth rate and equilibrium density $(r_1 = r_2 \text{ and } \alpha_{11} = \alpha_{22})$.

This could represent a mutation to an interference competition trait, for example (Gill,

 599 1974). Then, according the above condition, for N to remain constant over the sweep, the 500 mutant must find the wildtype more tolerable than itself by exactly the same amount that 601 the wildtype finds the mutant less tolerable than itself.

Even if we persuaded ourselves that this balance of inter-type interactions is plausible in some circumstances, when multiple types are present the requirement for constant N becomes

$$\sum_{ij} r_i (\alpha_{\text{intra}} - \alpha_{ij}) p_i p_j = 0, \tag{34}$$

which depends on frequency and thus cannot be satisfied in general for constant inter-type coefficients α_{ij} . Therefore, Lotka-Volterra selection will generally involve non-constant N.

Appendix C: Density-dependence of b-selection

In section "Density-regulating traits and the threat of strong selection" we argued that the density-dependent factor $f(\bar{b}, N)$ is unchanged at the beginning and end points of an equilibrium-to-equilibrium b. Here we estimate the magnitude of the deviation in $f(\bar{b}, N)$ during the sweep.

For simplicity, we introduce the notation D = N/T and assume that D is small. We can thus make the approximation $1 - e^{-\bar{b}D} \approx \bar{b}D$ and $f(\bar{b}, N) \approx \bar{b}(1 - D)$. We expect this to be a conservative approximate based on the worst case scenario, because N is most sensitive to an increase in b in this low-density linear regime. We first calculate the value of $f(\bar{b}, N)$ at the halfway point in a sweep, where the halfway point is estimated with simple linear averages for b and N. The sweep is driven by a b variant with $b_j = b_i(1 + \epsilon)$, and we denote the corresponding initial and final densities by D_i and D_j respectively, where we

have $d_i = b_i(1 - D_i) = b_j(1 - D_j)$. We obtain

$$f_{\text{half}} = f(\frac{b_i + b_j}{2}, \frac{N_i + N_j}{2}) = \frac{b_i + b_j}{2} \left(1 - \frac{D_i + D_j}{2} \right)$$

$$= \frac{1}{4} (b_i + b_j)(2 - D_i - D_j)$$

$$= \frac{1}{4} (2d_i + b_i(1 - D_j) + b_j(1 - N_i)). \tag{35}$$

Dividing by d_i , the proportional deviation in f(N) at the midpoint of the sweep is

$$\frac{f_{\text{half}}}{d_i} = \frac{1}{4} \left(2 + \frac{b_i}{b_j} + \frac{b_j}{b_i} \right)
= \frac{1}{4} \left(2 + \frac{1}{1+\epsilon} + 1 + \epsilon \right)
= 1 + \frac{1}{4} (\epsilon^2 - \epsilon^3 + \dots),$$
(36)

where we have used the Taylor expansion $\frac{1}{1+\epsilon} = 1 - \epsilon + \epsilon^2 - \epsilon^3 + \dots$

By contrast, for a δ sweep in Eq. (11), the density-dependent term N increases by a factor of $\frac{1}{1-\epsilon} = 1 + \epsilon + \epsilon^2 + \ldots$ Thus, the deviations in f(N) are an order of magnitude smaller than those shown in Fig. (6).
